Pathobiology of Acute Myocardial Ischemia: Metabolic, Functional and Ultrastructural Studies

KEITH A. REIMER, MD, PhD, ROBERT B. JENNINGS, MD, and ARTHUR H. TATUM, MD, PhD

Acute myocardial ischemia induced by coronary occlusion in dogs is most severe in the subendocardial region, whereas more collateral blood flow is often present in the subepicardial region. Initially, all ischemic myocytes are reversibly injured, but beginning at 15 to 20 minutes after the onset, and continuing for 3 to 6 hours, there is a wave front of cell death from the subendocardial region to the less ischemic subepicardial region, such that by 6 hours, the final transmural extent of the infarct is established. Thus, ischemic myocardium cannot be salvaged by reperfusion after ≥6 hours of coronary occlusion in open-chest anesthetized dogs.

In the severely ischemic subendocardial region, most of the creatine phosphate is lost within the first 3 minutes of ischemia in vivo, and adenosine triphosphate (ATP) is depleted to 35% of control by 15 minutes (when cellular injury is still reversible), and to <10% of control at 40 minutes (when injury is irreversible). Tissue ATP content and other indexes of subcellular damage have also been compared after different periods of ischemia using a model of total myocardial ischemia in vitro. As long as the ATP of the tissue was not depleted below μmol/g dry weight, incubated slices of injur myocardium resynthesized high-energy phosphat and excluded inulin. However, lower tissue ATP w associated with depressed high-energy phospha resynthesis and failure of cell volume regulatic Overt membrane damage, as measured by an i creased inulin-diffusible space, was detected or after the tissue ATP decreased to <2.0 μmol/g dry weight. Thus, marked ATP depletion is assoc ated with the onset of structural and functional i dexes of irreversible injury. However, whether reversibility is caused by the marked ATP depleti or by other concomitant metabolic consequenc of ischemia is not known. Myocardial ischem cellular injury is reversible despite depletion of 70 of the control ATP. Nevertheless, when myocy injury is reversible, there is slow repletion of adeni nucleotides. This slow metabolic recovery m explain the delayed recovery of contractile functi observed after reperfusion of ischemic myoca dium.

Severe ischemia has been defined as a reduction in coronary arterial blood flow to ≤15% of control.[1] In the dog heart, this develops in the subendocardial region of the myocardium when the circumflex artery supplying this region is occluded near its origin. Myocytes will tolerate 15 minutes of ischemia of this severity, that is, they survive if flow is restored after this interval. Thus, the injury induced by up to 15 minutes of severe ischemia is *reversible*.[2] In contrast, if ischemia is allowed to persist for 40 minutes before arterial flow is restored, many of the cells in the subendocardial region of seve ischemia die. The cells that do not survive when isch mia is eliminated undergo phagocytosis and are replac by scar tissue; thus, the injury is *irreversible*.

By 40 minutes of ischemia, cell death in the sube docardial region extends to within 1 to 2 mm of t lateral edge of the ischemic vascular bed; thus, in th region there is no lateral border zone of myocardiu salvageable by reperfusion.[3] In contrast, myocytes in t subepicardial region, where collateral blood flow greater, can be salvaged by reperfusion at 40 minute but will undergo infarction if the ischemia is allowed persist for ≥3 hours. Thus, the onset of irreversib ischemic cell injury does not occur simultaneously in a regions but develops as an expanding transmural wa front of cell death (Fig. 1).[3,4] Although there is no wa to prove this in man, it seems likely that a similar wa

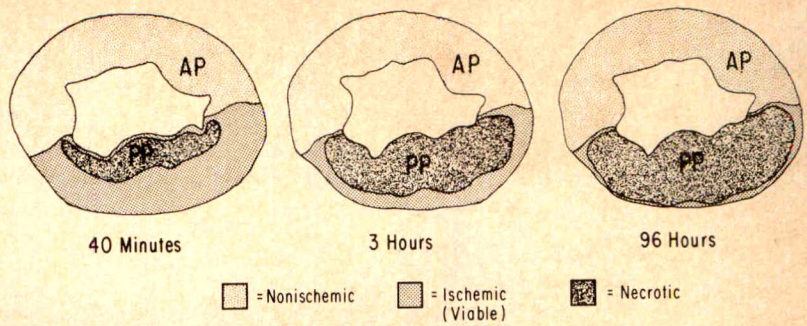

FIGURE 1. Progression of cell death versus time after occlusion of the circumflex artery in open-chest dogs. Necrosis occurs first in the subendocardial myocardium. With longer occlusions, a wave front of cell death moves from the subendocardial zone across the wall to involve progressively more of the transmural thickness of the ischemic zone. Thus, there is typically a large zone of subepicardial myocardium in the ischemic bed that is salvageable by early reperfusion but that dies in the absence of such an intervention. In contrast, the lateral margins in the subendocardial region of the infarct are established as early as 40 minutes after occlusion and are sharply defined by the anatomic boundaries of the ischemic bed. Reproduced from Reimer and Jennings[3] with permission of the publisher. AP = anterior; PP = posterior.

front of injury occurs after coronary occlusion in the human heart. In addition, the time course of cell injury in man only can be inferred from indirect indexes of ischemic injury. Nevertheless, animal data such as these provide a rational basis for early intervention in an evolving myocardial infarction and particularly for reperfusion through thrombolysis.

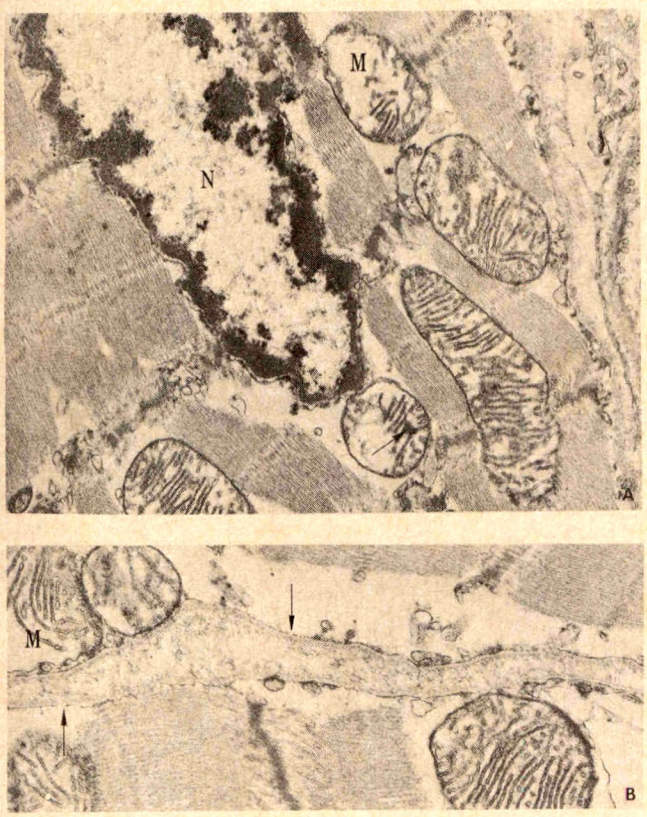

FIGURE 2. Posterior papillary muscle after 40 minutes of ischemia. **A,** the significant alterations from control include the marked margination of nuclear chromatin (N) and mitochondrial swelling (M) with the appearance of a clear matrix which often contains amorphous matrix densities (**arrow**). No glycogen is detectable. **B,** several small breaks are visible in the plasma membrane although the glycocalyx appears continuous. Swollen mitochondria (M) are present. The myofibrils are relaxed and show I bands. Original magnification: A ×31,000, B ×38,000; reduced 52%. Reproduced from Jennings et al[13] with permission of the publisher.

One of the major interests of our laboratory has been to characterize events associated with the transition from reversible to irreversible injury, with the aim of establishing the mechanism of ischemic cell death. To study this problem, we have confined our studies to the subendocardial region of severe ischemia and have compared myocardium reversibly injured by 15 minutes of ischemia with myocardium irreversibly injured by 40 minutes of ischemia.

Events During the Reversible Phase of Ischemic Injury

The onset of ischemia is accompanied by rapid changes in both myocardial metabolism and function.[5] Within the first 10 to 15 seconds after the occlusion, the tissue partial oxygen pressure decreases, mitochondrial respiration is inhibited, and the myocytes begin to use anaerobic glycolysis as the principal source of new high-energy phosphate (HEP). As a consequence, cellular glycogen levels decrease and lactate begins to accumulate in the ischemic tissue.

Contractile activity stops within 10 to 15 seconds of the onset of severe ischemia. Thus, ischemia induces an almost immediate effect on contractile function at a time when all myocytes still are viable and before much ATP depletion has occurred. Thus, loss of contractile function is not necessarily related to irreversibility. Severe ischemia is associated with the progressive loss of the cellular pool of HEPs, even though utilization of HEP by contractile activity is reduced or absent, for 2 reasons. First, anaerobic glycolysis can produce only 3 ATP molecules per glucosyl unit of glycogen converted to lactate, versus the 38 molecules of ATP produced with complete aerobic metabolism of glucose. In addition, after a brief burst of lactate production, the rate of anaerobic glycolysis is limited by end-product inhibition at ≥1 enzymatic steps. In part, the increasing lactate/pyruvate ratio slows the conversion of pyruvate to lactate so that the NADH/NAD (nicotinamide–adenine dinucleotide) ratio increases and glycolysis becomes inhibited at the glyceraldehyde-3-phosphate dehydrogenase level.[6] In addition, phosphofructokinase is inhibited by acidosis and high lactate concentrations.[7–9]

Thus, the metabolic consequences of severe ischemia result both from the reduction in substrate and oxygen

delivery and from the failure to remove end products of metabolism. In this regard, severe ischemia differs from hypoxia or mild ischemia. In the latter conditions, metabolites are removed from the tissue by continued perfusion. Because of this difference, the rate of anaerobic glycolysis is much faster in hypoxia with continued flow than it is in severe ischemia.[10,11]

Events Associated With the Onset of Irreversible Injury

We have identified several features of ischemic myocardium that are not present in reversibly injured myocytes, but which appear at about the time of the onset of irreversible injury[12]: (1) ATP is almost completely depleted.[13] (2) Mitochondria are swollen and contain amorphous matrix densities.[14] The latter are composed principally of lipid and perhaps contain protein; their functional significance and origin are uncertain.[15] (3) There is evidence of damage to the sarcolemma. Small breaks in the sarcolemma can be seen by electron microscopy.[13,16] Membrane defects also can be demonstrated in vitro by incubating slices of injured myocardium in an oxygenated Krebs-Ringer's phosphate medium. In such slices, intracellular components such as creatine are lost and the inulin-diffusible space expands, indicating increased membrane permeability to inulin.[17] Reperfusion of irreversibly injured cells in vivo results in explosive cell swelling of myocytes associated with massive influx of Ca^{++}.[18,19]

The ultrastructural characteristics of irreversible myocyte damage that are seen in severely ischemic myocardium 40 minutes after coronary occlusion in vivo are illustrated in Figure 2. Nuclear chromatin is clumped and mitochondria are swollen and contain amorphous matrix densities. In addition, small breaks are evident in the plasmalemma of the sarcolemma. These changes are characteristic of irreversibly injured myocardium, whether or not reperfusion has been established.

If the irreversibly injured myocardium is reperfused in vivo or reoxygenated in vitro, rapid changes occur which are termed explosive cell swelling[19] (Fig. 3). There are large subsarcolemmal blebs and the sarcolemma is severely damaged, often with areas in which scattered vesicles are the only remnants of the plasmalemma still attached to the glycocalyx. The severe membrane damage is associated with massive calcium overload.

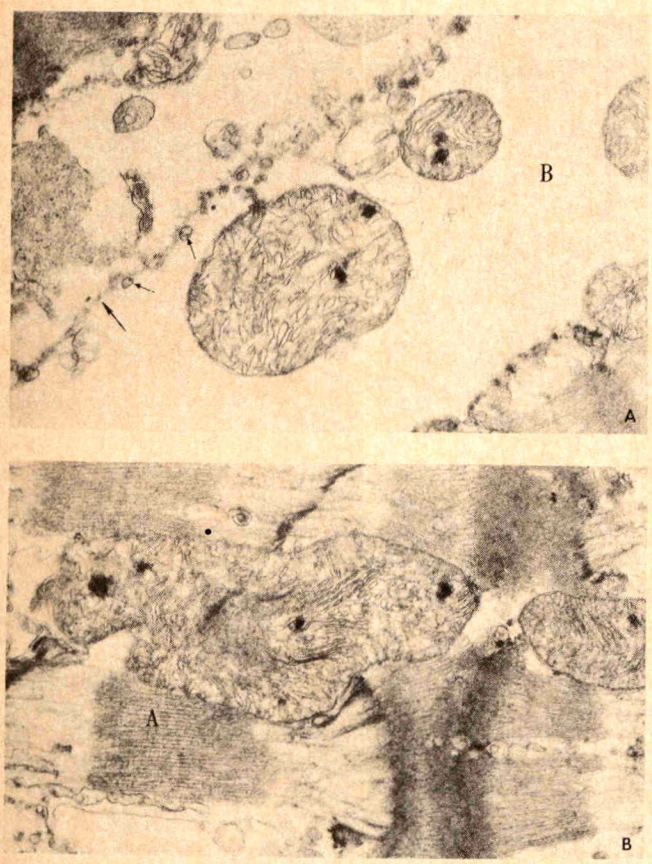

FIGURE 3. Posterior papillary muscle after 60 minutes of in vivo ischemia and 60 minutes of reoxygenation by slice incubation in vitro. **A,** a large subsarcolemmal bleb (B) that contains 2 mitochondria, each of which contains large, amorphous matrix densities. The remains of the sarcolemma show glycocalyx and circular profiles of plasma membrane (**arrows**). **B,** foci of hypercontraction of myofibrils. Two Z lines appear to be included in the aggregate at lower right, while an isolated A band (A) is seen at lower left between 2 superstretched I bands. A large mitochondrion contains several amorphous matrix densities. Original magnification: A and B ×28,000; reduced 52%. Reproduced from Jennings et al[13] with permission of the publisher.

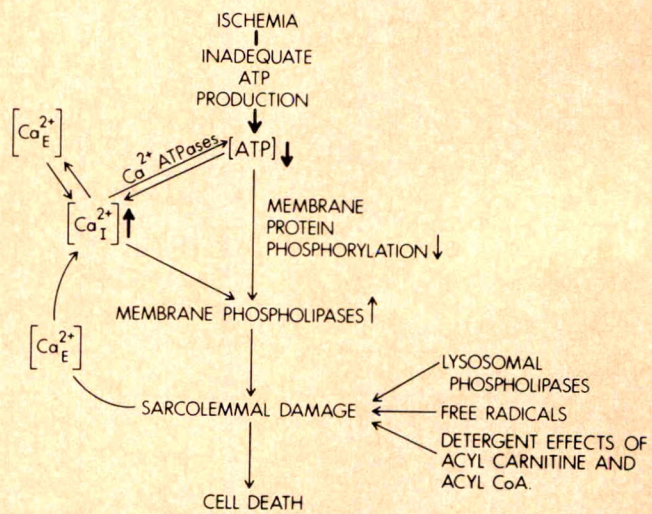

FIGURE 4. The potential relationships between ATP depletion, Ca^{++} influx, and sarcolemmal damage, which form the basis for various hypotheses of the events leading to sarcolemmal damage. The ATP of ischemic myocytes decreases because ATP utilization exceeds the capacity of anaerobic glycolysis to produce high-energy phosphates (HEP). Intracellular Ca^{++} (Ca^{2+}_i) may increase either because of increased membrane permeability to Ca^{++} or because of inadequate ATP to support the mechanisms responsible for Ca^{++} extrusion from the cell or sequestration of Ca^{++} by the sarcoplasmic reticulum. Increased Ca_i^{++} also may accelerate ATP depletion through Ca^{++} activated ATPases. Sarcolemmal damage occurs at ATP levels of 3 to 8% of control. The mechanism of damage is unknown. One explanation is activation of endogenous sarcolemmal phospholipases by the increased Ca_i^{++} or depressed phosphorylation of membrane proteins that ordinarily inhibit the activity of the endogenous phospholipases of the sarcolemma. Lysosomal phospholipase release, free radicals, or the detergent action of acyl carnitine or acyl coenzyme A also are possible causes of sarcolemmal damage in myocardial ischemia. Reproduced from Jennings and Reimer[12] with permission of the publisher.

Sarcomeres are supercontracted and the myofibrillar apparatus is disrupted with formation of contraction bands. Mitochondria accumulate some of the excess calcium, which is deposited as intramitochondrial crystalline densities.

Numerous hypotheses, which often are interrelated, have been proposed to explain the transition to irreversibility.[12] The most popular hypotheses focus on membrane damage (Fig. 4). The lethal event is considered to be disruption of the sarcolemma and perhaps other membrane systems of the cell; accordingly, the proximate cause of irreversibly would be the sequence of events that leads to functional and structural disruption of the membranes. The 2 major consequences of damage to the sarcolemma are the entry of excess Ca^{++} into the myocyte from the extracellular space, with resultant disruption of much of the internal metabolic machinery of the cell,[1,20] and the loss of critical intracellular components such as enzymes and cofactors through a leaky membrane to the extracellular space.[21] The causes of membrane disruption are unknown. Those proposed include activation of endogenous phospholipases of the sarcolemma as a consequence either of increased intracellular Ca^{++} [22] or of depressed phosphorylation of membrane proteins by the reduced sarcoplasmic ATP of the ischemic cell.[13] Alternatively, membranes could be damaged because of the action of phospholipases released from lysosomes, the detergent action of acyl carnitine and acyl coenzyme A, which accumulate in ischemia,[23] free radical effects such as lipoperoxidation,[24] or failure to resynthesize membranes lost through pinocytosis or other processes (turnover without replacement).

Mitochondrial defects also are a characteristic of the irreversible state and represent another potential cause of the transition to irreversibly.[15] Mitrochondrial function is inhibited in the absence of oxygen. Thus, mitochondrial damage would be of no added consequence as long as the tissue was severely ischemic. However, reoxygenation of ischemic myocardium must be followed by resumption of integrated mitochondrial function if the myocytes are to remain viable and recover contractile function.

Our working hypothesis is that cell death occurs when HEP (principally ATP) is depleted to levels insufficient to maintain the cell's structural integrity. Because HEP, in the form of ATP, is required for a large number of synthetic and degradative reactions within the cell, the premise that ATP is required to keep a cell functional and alive is generally accepted. However, the converse hypothesis, that the absence of HEP is the proximate cause of cell death, is unproved. The principal support for this hypothesis is circumstantial, that is, the close temporal relationship between HEP depletion and lethal myocardial ischemic injury.[13] This relationship will be described in more detail later. However, proof of this hypothesis will require the identification of ≥ 1 reactions that require ATP, the absence of which causes ischemic injury to become lethal. ATP is clearly essential for a wide variety of homeostatic mechanisms. In particular, ATP is essential for regulation of cellular Ca^{++} content and compartmentation.[21] In addition, low levels of sarcoplasmic ATP result in activation of phospholipases and depletion of mitochondrial adenine nucleotides causes the loss of phosphorylating capacity.[25] Alternatively, other metabolic consequences of ischemia unrelated to ATP depletion that could contribute to the cellular injury in ischemia include the accumulation of lactate or lactic acid[26,27] and acidosis.[28]

High-Energy Phosphate Production, Utilization and Depletion in Ischemia

Within seconds after the onset of severe ischemia, the available oxygen in the tissue is depleted and mitochondrial respiration is inhibited. Thereafter, any HEP utilized by the cell must come either from preexisting stores of ATP or creatine phosphate (CP) or from anaerobic glycolysis. Preexisting stores of HEP include 8 μmol of CP,[29] 5.8 μmol of ATP, and 1.2 μmol of ADP per gram of wet tissue weight. Because of the myokinase reaction, both HEP bonds at ATP can be utilized by the cell. Thus, the total preexisting store of HEP is about 20 μmol/g. Myocardium also contains about 44 μmol of glycosyl units of glycogen/g.[5] Each of these glucosyl

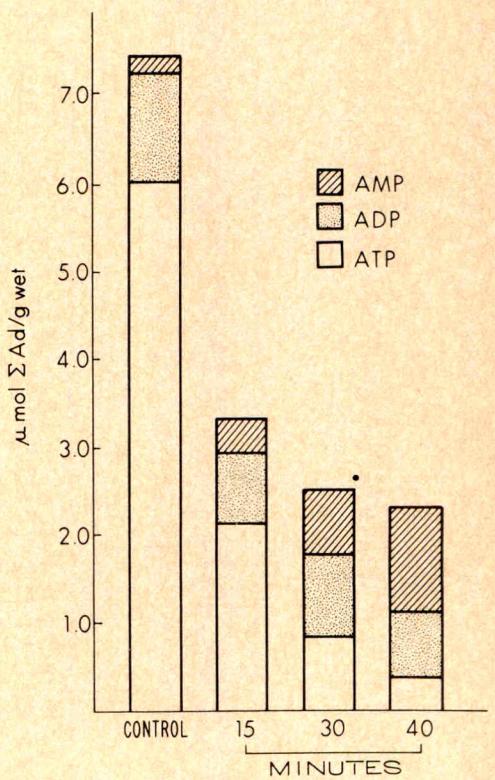

FIGURE 5. The adenine nucleotide contents of normal and severely ischemic myocardium of dogs subjected to proximal occlusion of the circumflex branch of the left coronary artery. Three to 5 dogs were used for each time point. Control data were pooled from all dogs. The ischemic tissue was obtained from the projecting portion of the posterior papillary muscle and the control nonischemic tissue came from the anterior papillary muscle. Intravenous thioflavine-S was used to identify the severely ischemic tissue and thereby exclude normal or mildly ischemic cells from the samples. After 40 minutes of ischemia, when most of the cells in this ischemic region are irreversibly injured, only 6% of the initial ATP remained and there was a 69% decrease in total adenine nucleotides. The data are plotted from Table 2 of Jennings et al.[13]

units can be metabolized to 2 μmol of lactate and, with the production of each micromole of lactate, 1.5 μmol of ATP are produced. If all the glycogen were consumed, 132 μmol/g of HEP could be produced. Thus, at the onset of ischemia, myocardium has a potential reserve of about 150 μmol of HEP/g.

ATP utilization is reduced markedly in ischemic myocardium because contractile function is suppressed. However, ATP continues to be consumed by various ATPases involved in the maintenance of cell volume and electrolyte gradients, in calcium homeostasis, and by other metabolic reactions. In severe ischemia, because the utilization of ATP always exceeds production, tissue levels decrease.[12]

The rapidity with which ATP is depleted from severely ischemic myocardium in vitro is illustrated in Figure 5. The ATP content decreases very rapidly to about 35% of control levels by 15 minutes (when the cells are still viable) and to <10% by 40 minutes (when the cells have been irreversibly injured).[13]

To study energy metabolism during ischemia in more detail, we also used a model of total ischemia in vitro.[5,17] Total ischemia is produced by excising normal hearts from dogs and simply keeping blocks of left ventricular myocardium in a moist environment at 37°C. In thi model, as in severe ischemia in vivo, there is progressiv depletion of ATP, parallel degradation of adenine nu cleotides, and accumulation of lactate (Fig. 6 and 7) The only difference is that these events occur mor slowly in vitro than in vivo.[5]

In both severe and total ischemia, the rate of lactat production was much less than the maximal rate tha could have been achieved if the end products of anaerobi glycolysis were washed out (Fig. 7). Nonetheless, gly colysis provided about 80% of the HEP utilized by th totally ischemic myocardium during the first 90 min utes. Thereafter, lactate production virtually stopped This occurred when only 50 to 60 μmol/g of lactate hac accumulated, that is, much less than the 88 μmol/g ex pected from the complete utilization of the glycoger known to be present in the tissue. This complete inhi bition of lactate accumulation followed the virtua complete depletion of ATP.

Possible explanations for the inhibition of anaerobi glycolysis late in ischemia include degradation o washout of cofactors such as NAD, or the inactivatio or inhibition of ≥1 enzymes of the glycolytic scheme Lack of substrate is an unlikely explanation becaus

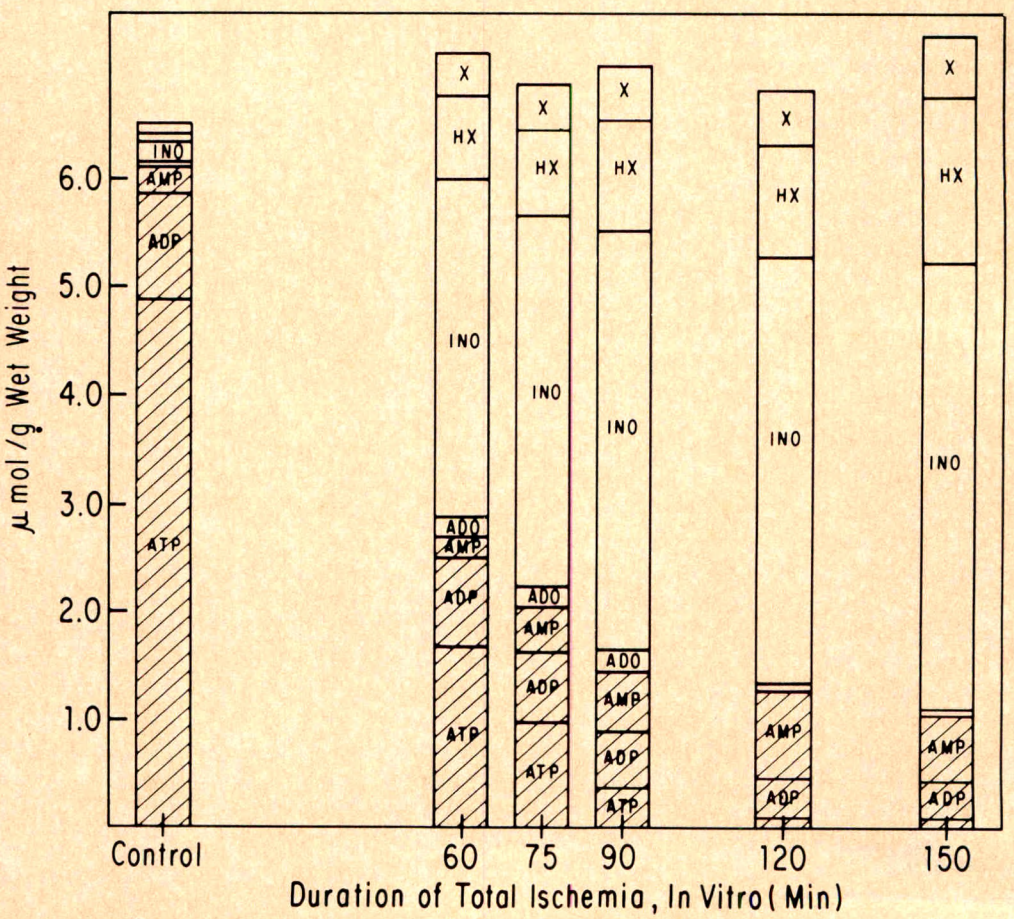

FIGURE 6. The decrease in ATP, ADP and ΣAd (ATP, ADP, plus AMP) that occurs as a function of the period of total ischemia. The decrease in the ΣAd was accounted for by a marked increase in the content of inosine (INO), hypoxanthine (HX), and xanthine (X). Reproduced from Jennings et al[5] with permission of the publisher.

glycolysis ceased even though some glycogen and a significant amount of glucose-6-phosphate remained in the tissue. The concurrence of severe ATP depletion and cessation of lactate production suggests that depletion of ATP levels below that required to phosphorylate fructose-6-phosphate to fructose-1,6-diphosphate is the most likely explanation for inhibition of anaerobic glycolysis.

ATP Depletion Versus Signs of Sarcolemmal Damage

Other signs of the onset of irreversible injury appear at or after the virtual depletion of ATP. For example, the relation between the ATP content of totally ischemic myocardium and the capacity of slices of this injured tissue to exclude inulin or to retain creatine is illustrated in Figure 8. We consider an increased IDS and decreased creatine content to be signs of increased membrane permeability, and, when marked, to be objective evidence of cell death. This evidence of membrane damage did not develop in any slice with a starting ATP >2.0 μmol/g. Thus, cell death is preceded by the cessation of energy utilization occasioned both by loss of HEP stores and inhibition of further HEP production through anaerobic glycolysis. A similar association between ATP depletion and increased membrane permeability to trypan blue has been observed in anoxic isolated rat heart myocytes.[29]

Structural Recovery Versus Slow Repletion of ATP After Brief Periods of Ischemia (Reversible Injury)

As noted earlier, 15 minutes of severe ischemia causes reversible injury in the sense that reperfusion will prevent the death of the ischemic cells and will restore the slight alterations in ultrastructure toward normal.[19] We have compared the ultrastructural appearance of myocardium that had been made severely ischemic for 15 minutes and then was reperfused for 24 hours with nonischemic myocardium from the same hearts. Figures 9 and 10 show representative changes seen among hearts from 4 dogs studied at this time interval; Figure 10 demonstrates the most severe changes found. No persistent cellular damage was observed. Nuclei and myofibrils were normal in both ischemic-reperfused and

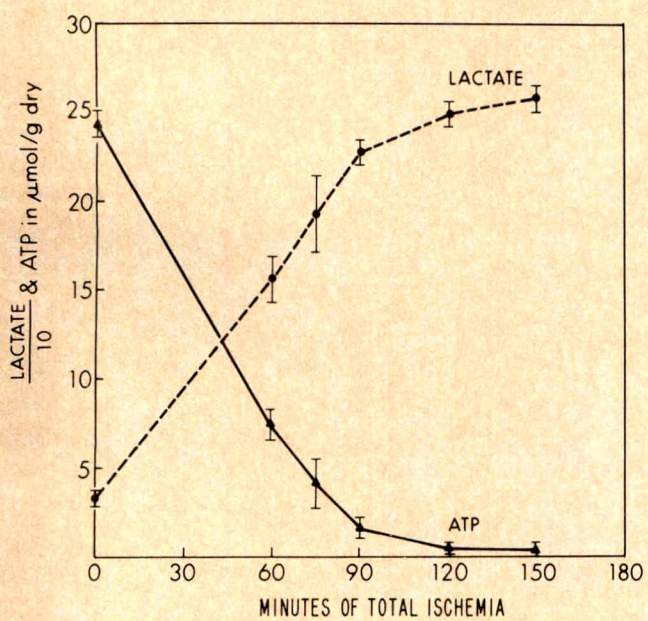

FIGURE 7. The ATP and lactate content of papillary muscles of dog hearts after varying periods of total ischemia. The hearts were quickly removed from the anesthetized dogs. Both left ventricular papillary muscles were excised quickly and, after obtaining control samples, were incubated at 37°C in a moist environment. The results are reported on the basis of dry weight, but can be divided by 5 to provide approximate results on the basis of wet weight for comparison with other studies illustrated in this paper. ATP degradation and lactate production ceased almost simultaneously at 90 minutes. The results are the mean of 4 to 6 animals at each point. The **bars** represent the standard error of the mean. Reproduced from Reimer et al[17] with permission of the publisher.

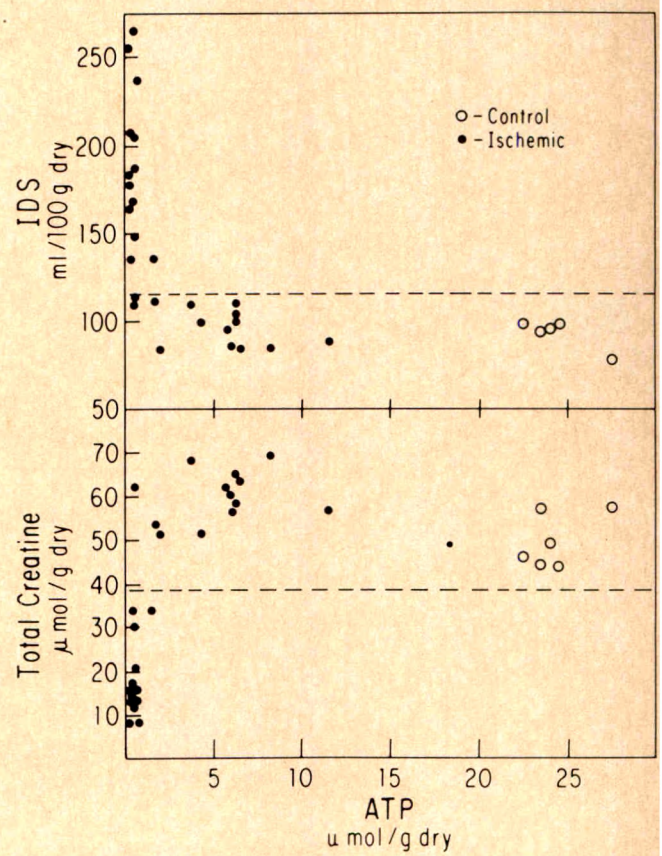

FIGURE 8. The capacity of control or injured slices to exclude inulin or retain creatine compared with the ATP content of the tissue before incubation. The **dashed lines** mark 2 standard deviations above and below the control mean inulin-diffusible space (IDS) and total creatine content, respectively. The data are plotted irrespective of the duration of total ischemia. Overt membrane damage, as indicated by increased permeability to these 2 markers, did not develop until the tissue ATP content was <2.0 μmol/g dry weight. Thus, overt membrane damage was manifest later than the defective regeneration of high-energy phosphates HEP. Reproduced from Reimer et al[17] with permission of the publisher.

nonischemic regions and no sarcoplasmic edema or vacuolization were detected. Most mitochondria also were normal. Occasional mitochondria from both ischemic reperfused and nonischemic regions showed slight swelling and a few mitochondria were enveloped by lysosomes. Such changes may be artifacts of tissue sampling or may be indicative of focal mitochondrial injury and increased turnover. Occasional perinuclear filamentous bodies of unknown origin also were seen in the ischemic-reperfused and occasionally in the nonischemic regions. In short, the similarity of ultrastructural findings in ischemic-reperfused and nonischemic regions indicate that 24 hours after reversible ischem injury, cardiac myocytes are structurally indistir guishable from control.

The data in Figure 5 show that although the injur is structurally reversible, 15 minutes of severe ischemi results in a 65% decrease in ATP.[13] In addition, th progressive reduction in tissue ATP content is para leled by destruction of the adenine nucleotides. Th major pathways of adenine nucleotide metabolism[30–3 are shown in Figure 11. The HEP bond remaining in th ADP molecule can be recovered by the myokinas (adenylate kinase) reaction, in which 1 ATP and adenosine monophosphate (AMP) molecule are pro duced from 2 ADP molecules. The resulting ATP i utilized and the remaining phosphate of AMP is cleave irreversibly by 5′-nucleotidase, resulting in adenosin and inorganic phosphate. The adenosine produce leaves the myocyte. Adenosine is a potent vasodilato this metabolic pathway may be responsible for th feedback control of myocardial blood flow. However, i the presence of continued severe ischemia, this step i responsible for the depletion of the cellular pool of ad enine nucleotides. The adenosine produced quickly i deaminated to inosine, the ribose moiety is cleaved t produce hypoxanthine, and a small amount of xanthin is produced as well.

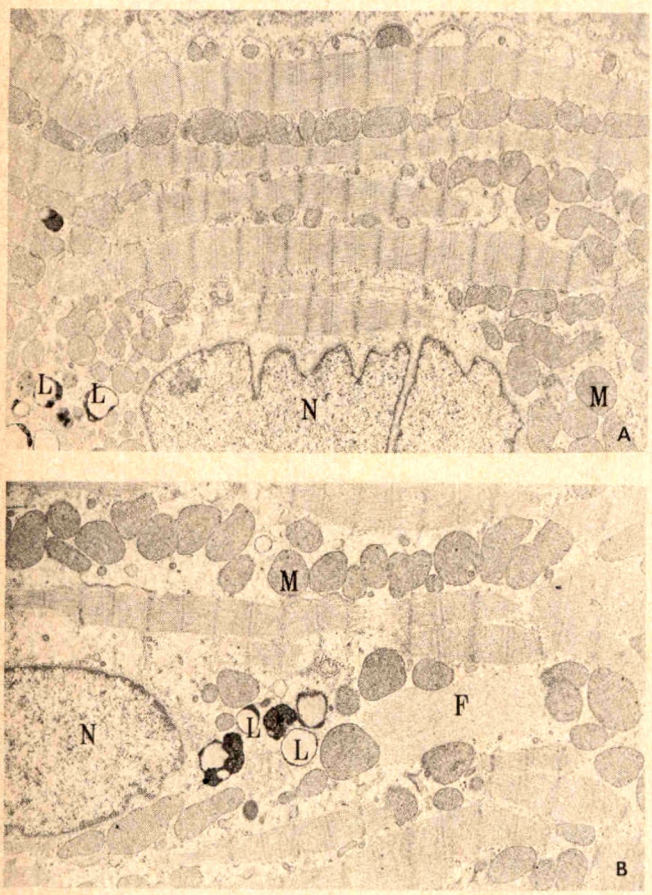

FIGURE 9. Nonischemic myocardium (**A**) from the anterior papillary muscle compared with myocardium from the posterior papillary muscle (**B**), which had been made severely ischemic by 15 minutes of circumflex artery occlusion and then was reperfused for 24 hours. The area of previous ischemia was identified by reoccluding the circumflex artery 15 seconds before excising the heart and injecting thioflavin-S intravenously. The posterior papillary samples were taken from the center of the nonfluorescent region of severe ischemia. Fixation was by immersion in 4% glutaraldehyde with postosmication. These illustrations are representative of findings among 4 dogs studied under these conditions. No striking differences between nonischemic and ischemic regions were observed. The nuclear (N) chromatin is evenly distributed, mitochondria (M) are abundant and generally have tightly packed cristae, and lysosomes (L) are intact. The myofibrils also are indistinguishable in the 2 regions. Neither contraction bands nor persistent relaxation were identified in any of the 4 dogs. A perinuclear filamentous body (F) of unidentified origin is present in B. Although not seen in the nonischemic region of this heart, similar structures were seen in both the nonischemic and ischemic samples of 2 of the other hearts. Original magnification: A ×10,400, B ×11,500; reduced 45%.

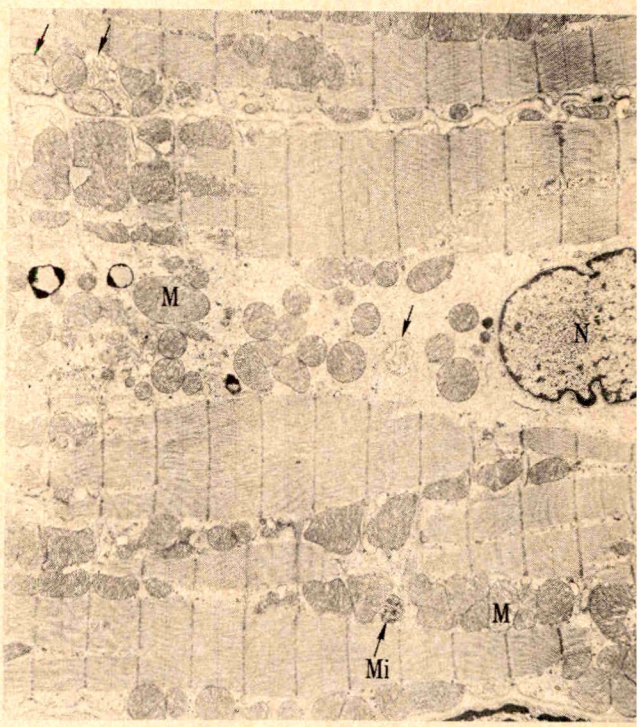

FIGURE 10. Myocardium after 15 minutes of circumflex occlusion an 24 hours of reperfusion (same experimental conditions as describe in Figure 9). This illustration is representative of the most marke changes seen in the previously ischemic region. The overall architecture is intact. However, a few mitochondria are swollen (**arrows**) and 1 mi tochondrion (Mi) contains amorphous matrix densities. The remaining mitochondria (M) are indistinguishable from control, as are the myofi brils, nuclei, sarcoplasm, sarcolemma and sarcoplasmic reticulum Original magnification ×9,675; reduced 47%.

Since the amount of the decrease in the adenine nucleotide pool was unexpectedly large in ischemia, we assessed the rate of net ATP and adenine nucleotide repletion after 15 minutes of severe in vivo ischemia, that is, late reversible injury.[33] The adenine nucleotide content of nonischemic and ischemic myocardium after 15 minutes of coronary occlusion is shown in Figure 12. The nonischemic nucleotide contents were similar to those measured in other laboratories.[29] By 15 minutes of coronary occlusion there was a 60% loss of ATP. ADP content was also slightly decreased. AMP was significantly increased, but this increase was quantitatively small compared with the ATP loss. Thus, total adenine nucleotides were reduced by 50%.

The effect that various periods of reperfusion after 15 minutes of ischemia had on tissue ATP content is shown in Figures 13 and 14. The ATP content of nonischemic myocardium was similar at all times studied. In the ischemic region, the ATP content increased slightly but significantly after 20 minutes of reperfusion. This early recovery of ATP is probably due to the recharging of the ADP and AMP remaining after the period of ischemia. However, no further increase in ATP content was detected even at 24 hours. By 4 days, the ATP level appoached, but still was significantly less than, the control level of ATP. This slow recovery of ATP content was paralleled by, and probably due to, the

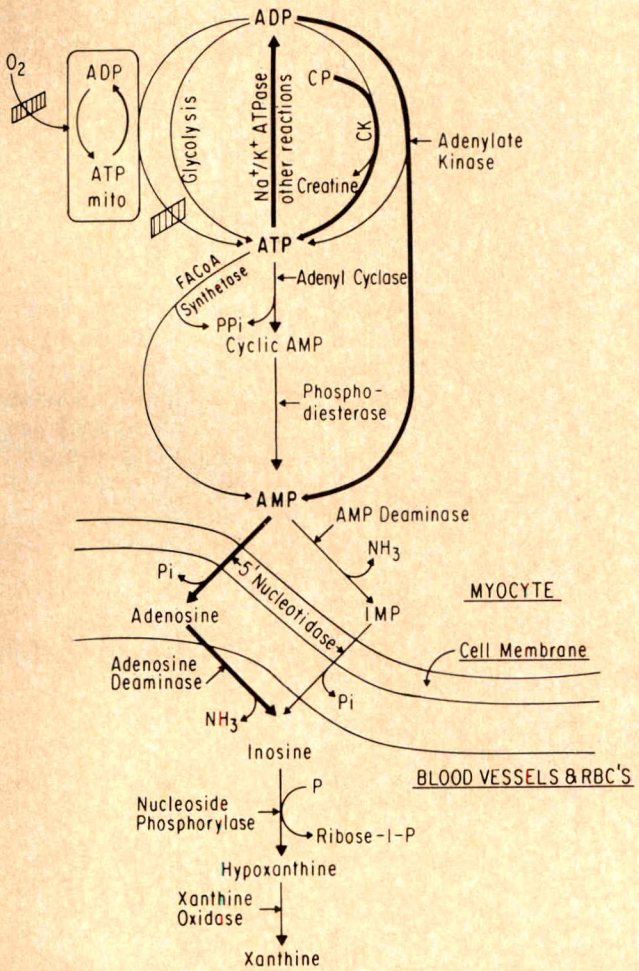

FIGURE 11. The major metabolic pathways of adenine nucleotide degradation during myocardial ischemia. The most quantitatively important pathways are indicated by the **solid thick arrows.** See text for further explanation. Reproduced from Jennings et al[5] with permission of the publisher. CP = creatine phosphate; ADP = adenosine phosphate; AMP = adenosine monophosphate; ATP = adenosine triphosphate.

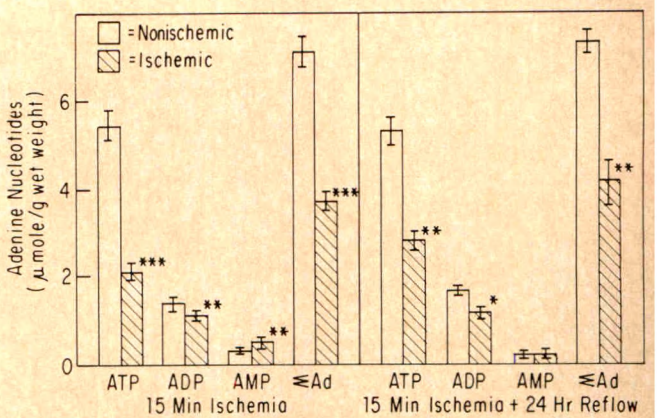

FIGURE 12. The effects of 15 minutes of ischemia without reperfusion (**left**) and with 24 hours of reperfusion (**right**) on total adenine nucleotides. After ischemia, ATP was reduced 60%. ADP was also reduced and although AMP was increased, the total adenine nucleotide content was decreased 50%. Nonischemic and ischemic samples from each dog were compared by paired *t* statistical analysis. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$. Reprinted from Reimer et al[33] with permission of the publisher.

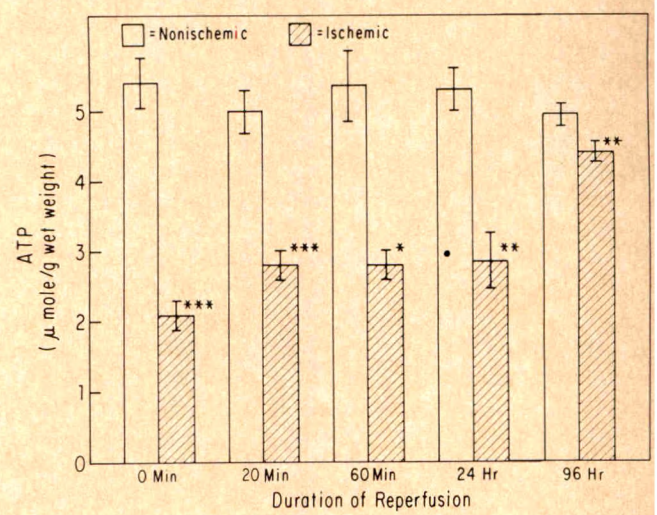

FIGURE 13. The effects of 15 minutes of ischemia with 0, 20 or 60 minutes and 24 or 96 hours of reperfusion of ATP content. ATP was markedly reduced in ischemic samples at all 5 times studied. ATP content increased slightly during the first 15 minutes of reperfusion, most likely because of rephosphorylation of ADP and AMP. ATP content showed no additional increase over the next 24 hours and was still slightly decreased at 96 hours. Brackets indicate the standard error of the mean. Nonischemic and ischemic samples from each dog were compared by paired *t* statistical analysis. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$. Comparison between groups using a nonpaired *t* test showed significant increases in ATP with all times of reperfusion compared with no reperfusion ($p < 0.05$). **Open bars,** nonischemic; **hatched bars,** ischemic samples. Reproduced from Reimer et al[33] with permission of the publisher.

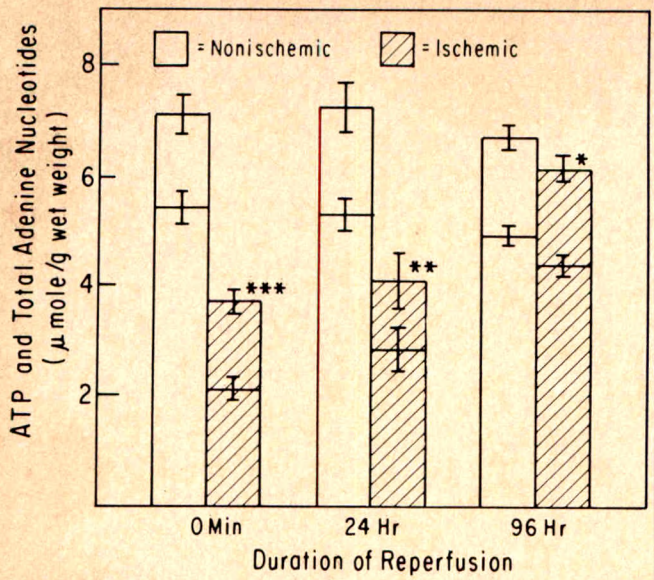

FIGURE 14. The effects of 15 minutes of ischemia and 0, 24, and 96 hours of reperfusion on total adenine nucleotide content. The total adenine nucleotide pool was still markedly reduced after 24 hours of reperfusion. By 96 hours, adenine nucleotide content had returned almost to normal, but was still significantly reduced compared with ischemic samples from the same hearts. The proportion of total adenine nucleotides in the form of ATP (from Figure 2) is indicated on each bar. Brackets indicate ± standard error of the mean. Nonischemic and ischemic samples from each dog were compared by paired *t* analysis. * $p < 0.05$, ** $p < 0.001$. Reproduced from Reimer et al[33] with permission of the publisher.

slow repletion of the total adenine nucleotide pool (Fig. 14). Both salvage and de novo pathways of adenine nucleotide synthesis are known to be slow in myocardium.[34,35]

These results have at least 2 major implications: (1) The delayed resynthesis of ATP may explain the slow functional recovery after brief periods of ischemia in experimental animals.[33,36–38] To the extent that the results are applicable to man, delayed resynthesis of adenine nucleotides may be one explanation why cardiac function often recovers slowly after cardiac surgery despite bypass of obstructed coronary arteries. (2) Repeated brief episodes of ischemia should have a cumulative effect on tissue ATP content. Thus, repeated episodes of angina probably have cumulative effects on the adenine nucleotide content of the affected myocardium, with possible functional consequences.

A variety of approaches have been tried with the aim of enhancing repletion of adenine nucleotides. Reibel and Rovetto[39] attempted without success to enhance postanoxic ATP regeneration in isolated perfused rat hearts either with ATP or adenosine. The explanation for their results may lie in the relative impermeability of the sarcolemma to ATP and the rapid catabolism of adenosine by way of the adenosine deaminase pathway. To overcome the latter problem, Foker et al[40] achieved enhanced recovery of ATP levels in ischemic dog hearts by combining adenosine with erythro-9-(2-hydroxy-3-nonyl) adenine hydrochloride, an inhibitor of adenosine deaminase. Alternatively, Zimmer et al[41] showed that the rate-limiting step for either de novo or salvage synthesis of adenine nucleotides is the formation of phosphoribosyl-1-pyrophosphate in the hexose monophosphate shunt. By enhancing this pathway by providing ribose, adenine nucleotide synthesis has been enhanced in rats in which myocardial ATP had been depleted by isoproterenol or asphyxia.[42,43]

In conclusion, myocardial ischemia is associated with the progressive depletion of HEP and the adenine nucleotide pool. In the subendocardial region of severe ischemia, ATP content is reduced to <10% of control levels by 40 minutes of ischemia in vivo; this marked depletion of ATP coincides with the onset of cell death. Cell death is completed in this region by the time 6 minutes has elapsed.

The subepicardial region often receives more collateral blood flow, and cell death in this region may be delayed for 3 to 6 hours. Thus, there is a transmural wave front of cell death in myocardial ischemia. Successful intervention to protect ischemic myocardium should be expected to limit the transmural extent of a infarct and transform a potentially transmural infarct into a subendocardial one.

Modest depletion of ATP due to brief periods of transient ischemia may not result in cell death, but there may be partial depletion of the adenine nucleotide pool. Even though reperfusion is established, the slow repletion of this pool may prevent early recovery of HEP content, and thus may be responsible for prolonged depression of contractile function. This concept of prolonged functional depression despite reversible cellular injury may be important in a number of settings including cardiac depression after cardiac surgery, cardiac failure in patients with angina pectoris, and evaluation of the effects of thrombolytic agents in the early therapy of acute myocardial infarction. Since the long-term effects of reperfusion may not be immediately evident, evaluation several days later might provide a better end point to judge the outcome of thrombolytic therapy. Whether acceleration of the pathways for adenine nucleotide synthesis facilitates functional recovery in the situations mentioned earlier remains to be established.

Prognostic Value of Submaximal Exercise Radionuclide Ventriculography After Myocardial Infarction

JAMES R. CORBETT, MD, PASCAL NICOD, MD, SAMUEL E. LEWIS, MD, ROBERT E. RUDE, MD, and JAMES T. WILLERSON, MD

Submaximal exercise testing with radionuclide ventriculography (RVG) was performed in 117 patients before hospital discharge 17 ± 7 days (± standard deviation) after an acute myocardial infarction (MI). The hypothesis tested in these studies was that submaximal exercise testing coupled to RVG allows the identification of patients at risk for future ischemic events in the subsequent 6 months, irrespective of MI location and type. The sites of MI were characterized as anterior transmural in 33, inferior transmural in 39, limited nontransmural in 18, extensive nontransmural in 24 and indeterminant in 3. During 6 months of follow-up, 9 patients died, 14 had recurrent MI, 18 had refractory angina pectoris, 16 had limiting angina and 17 had congestive heart failure.

Discriminant function analysis ranked exercise changes in left ventricular (LV) ejection fraction and end-systolic volume the most important of all clinical, exercise and scintigraphic variables for predicting future cardiac events. The predictive accuracy of changes in LV ejection fraction and end-systolic volume were 93 and 91%, respectively, for the entire group, and were significantly more sensitive than any degree of ST-segment depression or elevation ($p < 0.001$). These findings were generally independent of MI location and type. Thus, submaximal exercise RVG after MI is an accurate means of identifying patients at risk for major cardiac events in the 6 months after hospital discharge.

An unfavorable prognosis after a myocardial infarction (MI) has been related to large infarct size, significant left ventricular (LV) dysfunction, anterior location of the MI, the transmural or nontransmural extent of the injury, and a prior MI.[1–13] When coupled with prior damage, an acute MI need not be large to result in a fatal outcome.[14] The extent and severity of coronary arterial stenoses and the functional state of the noninfarcted left ventricle also have been correlated with patient survival.[15,16] Therefore, the identification of the extent of damaged myocardium and "myocardium at risk" should provide prognostic information.[17,18] Radionuclide ventriculography (RVG) is an established noninvasive technique for measuring LV function.[19,20] Submaximal exercise testing with electrocardiography after MI provides prognostic information, presumably indicating "myocardium at risk."[18,21–25] In this study, we tested the hypothesis that submaximal exercise testing with RVG in patients after MI allows one to predict prognosis independent of the location or type of the MI.

From the Departments of Internal Medicine (Cardiovascular Division) and Radiology (Nuclear Medicine) at the University of Texas Health Science Center at Dallas and Parkland Memorial Hospital, Dallas, Texas. This work was supported in part by Ischemic SCOR Grant #HL-17669 from the National Heart, Lung, and Blood Institute, the National Institutes of Health, Bethesda, Maryland, and by the Harry S. Moss Heart Fund, Dallas, Texas.

Methods

Patients: All patients admitted to the coronary care unit of Parkland Memorial Hospital from August 1978 to January 1981 in whom a diagnosis of acute MI was made were considered for study. The 117 patients in this report represent approximately 50% of patients with acute MI admitted during this period. Patients with unstable angina after MI, severe congestive heart failure, musculoskeletal disorders impairing their ability to exercise, participation in other research protocols which might alter the results of exercise testing, or who refused to provide informed consent were excluded. Age, sex, systemic arterial hypertension (>180/100 mm Hg), therapy with digoxin, beta blockers or antiarrhythmics, and electrocardiographic abnormalities complicating interpretation of the ST segments were not considered reasons for exclusion. We obtained submaximal exercise tests with scintigraphy before hospital discharge to detect serious arrhythmias and severe myocardial ischemia developing with mild to moderate effort.[18,26,27]

TABLE I Clinical Characteristics (n = 117)

Age (yr)	25–80 (mean 53)
Men	78
Women	39

Anterior TM MI	33
Inferior TM MI	39
Limited NT MI	18
Extensive NT MI	24
Cardiac medications at SE ETT	93

MI = myocardial infarction; NT = nontransmural; SE ETT = submaximal exercise tolerance test; TM = transmural.

The study population consisted of 116 patients in whom sufficient follow-up information to assess clinical course and subsequent cardiac events was available for at least 6 months after MI (Table I). One additional patient was lost to follow-up after 3 months.

There were 78 men and 39 women with a mean age of 53 years (range 25 to 80). Thirty-six patients had a previous MI. The diagnosis of acute MI was based on electrocardiographic,[18] enzymatic (creatine kinase [CK] and CK-B isoenzyme),[28] and technetium-99m stannous pyrophosphate myocardial scintigraphic criteria.[29] Anterior MI was defined by the development of new Q waves, ST-T-wave changes or ≥50% loss in R-wave voltage in leads I, aVL, or V_1 to V_6. Inferior (or true posterior) MI was defined by similar changes in leads II, III and aVF or the development of R > S-wave amplitude in precordial leads V_1 and V_2. Transmural MI in all locations was diagnosed by the development of Q waves ≥0.04 second in duration, a Q ≥ 25% of R-wave amplitude, or a ≥50% loss in R-wave voltage.[30] Nontransmural (subendocardial) MI was recognized by the presence of ST- and T-wave abnormalities without the development of significant Q waves or R-wave loss. Using these criteria, 72 patients had transmural MI: 33 anterior and 39 inferior. Because of difficulties in accurately localizing nontransmural MI by the electrocardiogram, nontransmural MI changes limited to ≤4 of the precordial leads and leads I and aVL or only leads II, III, and aVF were classified as "limited nontransmural," and those that involved more leads were classified as "extensive nontransmural."[31] Forty-two patients had nontransmural MI, 18 limited and 24 extensive. Three patients had left bundle branch block and were classified as having an MI of indeterminant location and type.

Exercise testing: Exercise tests were conducted a mean of 17 ± 7 days (± standard deviation [SD]) after MI and were performed generally 1 or 2 days before hospital discharge. No attempt was made to alter medical therapy before exercise testing. Drug therapy at the time of testing consisted of digoxin (32 patients), propranolol (29 patients), long-acting nitrates (53 patients), and antiarrhythmic agents (36 patients). No patient had taken nitroglycerin for chest pain within 48 hours of testing. Exercise testing was performed in the supine feet-up position with a bicycle ergometer.[18] The Frank lead system[32] was used to monitor the electrocardiographic responses continuously during exercise in 75 patients and a standard 12-lead system was used in 43. Horizontal or downsloping ST-segment depression ≥0.05 mV or ST elevation ≥0.1 mV with the Frank lead system were considered indicative of ischemia.[33,34]

Blood pressures (by sphygmomanometer) at rest and near the completion of each exercise level were recorded. Graded exercise was performed beginning at 150 or 300 kpm and was increased by 150 to 300 kpm at each subsequent exercise level, depending on age, body habitus and performance at the earlier exercise levels. The duration of exercise was approximately 4 minutes at each work load. Exercise was continued until a target heart rate of 130 beats/min was achieved or one of the following endpoints was reached: (1) progressive chest discomfort compatible with angina pectoris, (2) complex ventricular arrhythmias,[35] (3) ST-segment depression of ≥0.2 mV compared with resting morphology, (4) decreasing systemic arterial blood pressure, or (5) incapacitating fatigue or dyspnea. Patients who developed angina or ST-segment displacement were allowed to complete the current exercise level whenever possible in order to complete scintigraphic data collection.

Radionuclide technique and imaging protocol: Multigated equilibrium blood pool imaging was performed after in vivo labeling of red blood cells with 30 mCi of technetium-99m sodium pertechnetate according to a standard technique.[26] Data collection was performed with a standard gamma scintillation camera (Ohio Nuclear Series 100) equipped with an all-purpose, parallel-hole collimator and interfaced with a dedicated on-line computer system (Ohio Nuclear VIP-450). Resting equilibrium gated blood pool scintigrams were obtained in multiple projections, including a modified 25 to 50° left anterior oblique projection as required for best septal definition and left ventricular isolation.

Scintigrams at rest and during submaximal exercise were acquired for a preselected time interval of 2 to 3 minutes and 90 to 100% of the cardiac cycle. Thirty-two frames/cycle with 75,000 to 150,000 counts/frame were acquired. Imaging began at each work load after the completion of 1 minute of exercise, which allowed the heart rate to stabilize and uninterrupted gating to proceed. At each work load during exercise, heart rate did not vary by >10% of the value recorded at the start of scintigraphic data collection.

Analysis of radionuclide ventriculograms: LV ejection fraction was calculated by a standard technique using the background-corrected activity from the regions of interest constructed over the ventricle at end-diastole and end-systole.[19] LV volumes were calculated by a nongeometric technique developed and validated by Dehmer et al[20,36] in our laboratory as well as by others. With this technique, LV volumes are calculated from the LV activity normalized for counts per milliliter of peripheral venous blood and acquisition time per frame. The arterial systolic blood pressure and LV end-systolic volume index (P/V index) was calculated by dividing the cuff-determined systolic blood pressure by LV end-systolic volume corrected for body surface area.[37]

A subjective analysis of LV segmental wall motion was obtained using a cinematic display of the entire cardiac cycle as well as a 2-frame display of end-diastole and end-systole. The LV was divided into 5 segments and each was graded according to the following scale: 4 = normokinesia, 3 = hypokinesia, 2 = severe hypokinesia, 1 = akinesia and 0 = dyskinesia.[18] The scores for all segments were summed at rest and at each exercise level, respectively, and the results are reported as a percentage of the maximal possible score.

Scintigraphic variables: The following measurements of LV function were evaluated for their ability to identify patients at risk for subsequent cardiac events: a resting LV ejection fraction <0.40, failure of the LV ejection fraction to increase by ≥0.05 during exercise, failure of the P/V index to increase by 35% during exercise, a >5% increase in LV end-systolic volume index during exercise, and a decrease in wall motion score during exercise.[37] An initial increase in LV ejection fraction with a subsequent decrease of ≥0.05 was considered significant even if the peak submaximal value was 0.05 greater than the resting value. Maintenance with exercise

TABLE II Clinical and Exercise Variable Correlates With Cardiac Events by 6-Month Follow-Up

NS = not significant.

of a resting LV ejection fraction ≥0.75 or a <0.05 increase were also considered normal responses.

Follow-up: The clinical course and hospital records of all patients were reviewed. Eighty-three patients were seen and examined by 1 of the investigators during the follow-up period. The hospital and clinic records of 20 patients cared for by other physicians at this institution were reviewed. Twelve patients and the immediate family of 6 patients (5 of whom had died) were interviewed by telephone. The mean follow-up period for all patients was 8.3 ± 5.1 months. Those who had no subsequent cardiac events were followed for 9.4 months (range 6 to 20), whereas those with subsequent cardiac events were followed for 7.3 months (range 1 to 24). Thirty-two patients with and 24 patients without subsequent cardiac events were followed for >6 months. We did not attempt to withhold or restrict medical therapy. For the purposes of this study, the following were considered important cardiac events: sudden death, cardiac death, recurrent myocardial infarction, episodes of unstable angina and medically refractory angina resulting in surgical intervention (hereafter referred to as "medically refractory angina"), persistent congestive heart failure, including episodes of pulmonary edema or persistent physical examination and radiographic evidence of congestive heart failure or both, and classic angina pectoris believed to interfere with preinfarction lifestyle ("limiting angina"). Death, recurrent MI and medically refractory angina were considered major cardiac events, whereas the others were considered minor events. Adequate follow-up was available on all patients at 6 months, with the single exception mentioned earlier. Follow-up was discontinued in patients who had coronary artery bypass surgery.

Statistical methods: Group comparisons of continuous variables are reported as the mean ± 1 SD. The analysis of intergroup differences was performed using a 1-way analysis of variance[38] and the appropriate multiple-range test for the continuous variables of interest.[39] Similarly, differences among groups in categorical variables were analyzed using Fisher's exact test[38] for equality of group proportions. McNemar's test[38] was used to compare the sensitivities of any 2 diagnostic techniques.

Stepwise discriminant analyses[40] were performed to assess the degree to which the clinical, exercise and RVG variables predicted the occurrence of subsequent cardiac events at 3- and 6-month follow-up. At each of the 2 follow-up periods, the patients were classified into 1 of 4 groups, based on the presence or absence of cardiac events: (1) no cardiac event; (2) any cardiac event; (3) minor cardiac event; and (4) ≥1 major cardiac event. In the discriminant analysis procedure, linear combinations of the predictor variables, called "classification functions," were obtained for the purposes of predicting group membership. The stepwise procedure enters these variables into the analysis successively on the basis of their discriminating power. At each stage of the procedure, the ability of the variables currently in the analysis to classify correctly the patients into the different groups is evaluated by determining the proportion of patients which are classified correctly. To adjust for possible bias, a "jack knife" validation procedure[40] was used which, in essence, classifies each of the current patients on the basis of a classification function that involves only the other patients in the study. Therefore, the discriminant analysis evaluation and the modification of this evaluation using the jack-knife procedure represent an attempt to classify patients using the variables described without influencing the classification results from this specific patient population.

Results

Clinical characteristics: There was no significant difference in age between patients with or without subsequent cardiac events. Female patients had a greater incidence of cardiac events (p = 0.014) (Table II). Patients with a history of MI also had a greater incidence of cardiac events (p = 0.003). Submaximal exercise-induced chest pain, ST depression of ≥0.1 mV and complex ventricular arrhythmias were not significant in distinguishing patients with cardiac events. ST-segment changes (depression ≥0.05 mV or elevation of ≥0.1 mV or both) were significant in predicting cardiac events (p = 0.002).

Clinical outcome: Seventy-four patients (63% of the study population) had at least 1 cardiac event during the 6-month follow-up. Nine of the 117 patients (8%) died (5 suddenly), 14 (12%) had recurrent MI and 18 (15%) had medically refractory or unstable angina that led to surgical intervention. Seventeen patients (15%) developed congestive heart failure and 16 (14%) had limiting angina despite medical therapy (Table III).

After 3 months of follow-up, cardiac events had occurred in 65 of the 74 patients who were to have events

within 6 months of follow-up. There was a tendency to progress from minor to major cardiac events over time; the number of patients with major cardiac events increased from 28 at 3 months to 41 at 6 months.

Bicycle exercise test and electrocardiographic results: No complications resulted from submaximal exercise testing in these patients. There were no significant differences in the maximal heart rate and blood pressure between patients with and without cardiac events, (Table III). The maximal work load performed was significantly greater in the patients without cardiac events (373 ± 195 versus 229 ± 109 kpm, $p < 0.01$).

Fifteen patients had chest pain and 78 patients had ≥0.05 mV ST depression or ≥0.1 mV ST elevation with submaximal exercise or both. Thirty-four of the 78 patients with ST changes had ≥0.1 mV of ST depression. The incidence of ST-segment depression of ≥0.05 mV or elevation ≥0.1 mV or both was greater in patients who eventually had cardiac events, although there were false-positive responses. Complex ventricular arrhythmias occurred in 8 patients, 5 of whom had cardiac events. Seven patients had both ST-segment changes and chest pain with exercise; all had cardiac events, 4 of which were major. Of the 34 patients with deep ST depression (≥0.1 mV), 25 had cardiac events, 14 of which were major, and 1 died.

Rest and exercise radionuclide ventriculography: LV ejection fraction, end-diastolic volume index (EDVI), end-systolic volume index (ESVI), normalized wall motion score and P/V index at rest and the percent change with exercise were determined. These and the peak submaximal exercise values for LV ejection fraction, ESVI, and P/V index are shown in Table IV. The LV ejection fraction, ESVI, and P/V index at rest and submaximal divided according to infarct distribution are shown in Figure 1. Patients with limited nontransmural infarcts had a significantly higher resting LV ejection fraction and P/V index and smaller ESVI than the other groups. During submaximal exercise, they tended to respond normally as a group. The anterior transmural infarct group had the most reduced LV function at rest and as a group had an abnormal response in each of these variables.

Predictive ability of scintigraphic parameters: Patients with cardiac events were compared with those without cardiac events to determine whether any of these variables identifies patients at risk for future ischemic events. Generally, the change with submaximal exercise in LV ejection fraction, ESVI, wall motion score and P/V index were significantly different in patients who had cardiac events compared with those who did not have them, irrespective of infarct distribution (Table IV, Fig. 2). Except for resting LV ejection fraction in the inferior transmural group, wall motion score in the limited nontransmural group and P/V index in the anterior transmural group, the resting LV ejection fractions, ESVIs, wall motion scores and P/V indexes were significantly different in the no-event and cardiac event groups ($p < 0.05$).

Patients without follow-up cardiac events had normal resting LV ejection fractions, EDVIs and ESVIs. They had only mild to moderate resting segmental wall motion abnormalities and reductions in P/V index. These patients tended to respond normally to submaximal exercise with an increase in LV ejection fraction, wall motion score and P/V index and a decrease in ESVI. A small increase in EDVI was found consistently in all infarct groups, independent of follow-up cardiac events.

Comparison of scintigraphic measurements: major versus minor events: The mean rest and peak LV submaximal exercise ejection fractions, ESVIs and P/V indexes for all patient groups according to the specific cardiac events that occurred during follow-up are shown in Figure 3. The peak submaximal exercise LV ejection fractions in the inferior transmural group

was significant in distinguishing major and minor cardiac events ($p < 0.05$). Otherwise, there were no consistent differences between major and minor event groups for these variables. The patients with limiting angina had the least abnormal and those patients that died and had persistent congestive heart failure the most abnormal findings (Fig. 3). In response to submaximal exercise, all the event groups had a similar response, and one essentially opposite to that in patients without cardiac events.

Predictive ability of clinical, submaximal exercise test and scintigraphic variables: A stepwise multivariate discriminant function analysis was conducted to test the ability of the clinical, exercise and

scintigraphic variables to predict future cardiac events (Table V). Table VI summarizes the results of this analysis and lists the "jack-knifed" percentage of patients classified correctly for all patients and the patients grouped according to infarct distribution.

Prediction: cardiac event versus no cardiac event: The change in ejection fraction with submaximal exercise was rated the most important variable in the first step of the discriminant analysis and classified correctly 89% of the 117 patients into event and no event groups. The ΔESVI with submaximal exercise was ranked a close second in the initial step of the discriminant analysis of all patients and was entered first in the analysis of limited and extensive nontransmural infarcts (Table VII), correctly classifying 84 and 96% of patients, respectively. As for the entire group, the ΔLV ejection fraction entered first in the inferior transmural infarcts and classified correctly 87%. In patients with anterior transmural MI, the LV ejection fraction at peak submaximal exercise entered first and classified 84% of the patients correctly.

Prediction: major cardiac event versus minor cardiac event: The discriminant function entered the same variables (ΔLV ejection fraction, ΔESVI and peak LV ejection fraction) in the initial step when separating patients into major and minor events and no-event groups. When this additional requirement was made, the ΔLV ejection fraction correctly classified only 61% in the first step. By the addition of LV ejection fraction at peak submaximal exercise, ST depression of ≥0.1 mV, the ΔESVI, work load completed during submaximal exercise and ΔEDVI, 74% were classified correctly. The analysis of the individual infarct groups showed 50 to 63% correctly classified in the initial step. The reduced discriminating power was primarily one of clas-

				5. ΔBP 94%	
				6. ΔWMS 100%	

BP = systolic blood pressure; ESVI = left ventricular end-systolic volume index; LVEF = left ventricular ejection fraction; NT = nontransmural; SE = submaximal exercise; ST = ST segment; TM = transmural; WMS = wall motion score; Δ = change with exercise; ↓ = depression.

sifying patients into the wrong event group, i.e., 10 of 33 with minor events were classified as major and, conversely, 12 of 41 with major events were classified as minor. Only 3 of 43 patients without cardiac events and 6 of 74 with cardiac events were misclassified.

Predictive ability according to degree of resting left ventricular dysfunction: The patients with anterior transmural MI had the most severe LV dysfunction with exercise (Fig. 1). Furthermore, the discriminant function entered the LV ejection fraction at peak submaximal exercise in the first step, unlike the other groups in which the ΔLV ejection fraction or ΔESVI entered first. Because of this, separate analysis of those patients with LV ejection fractions <0.40 and ≥0.40 were performed (Table VII). The LV ejection fraction at peak submaximal exercise entered first in the group with resting LV ejection fractions <0.40 and correctly classified 90% of patients into event and no event groups and 66% into major, minor and no-event groups. The analysis of those patients with LV ejection fractions ≥ 40% provided the same information as that described for the entire group of 117 patients (Table VI). It should be noted that 26 of 29 patients with LV ejection fractions <0.40 had cardiac events, whereas 48 of 88 patients with LV ejection fractions ≥0.40 had cardiac events (p <0.001).

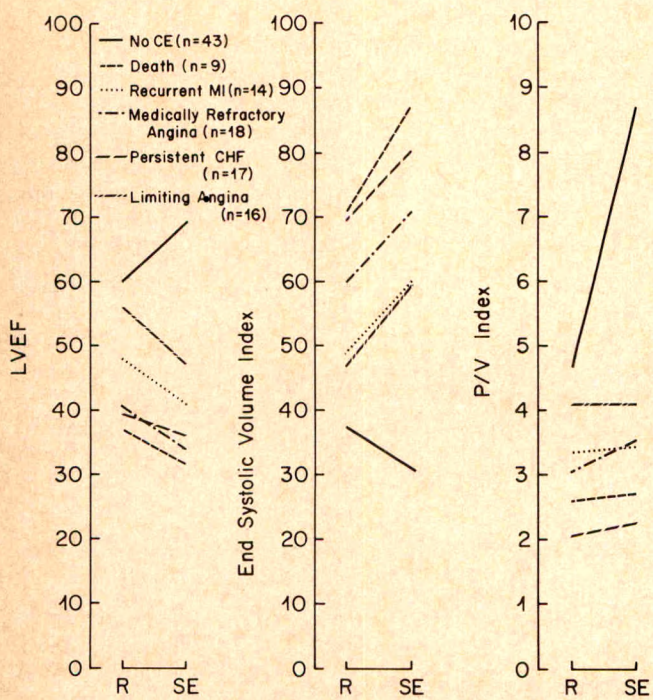

FIGURE 3. Left ventricular ejection fraction (LVEF), end-systolic volume index and pressure/volume (P/V) index at rest (R) and peak submaximal exercise (SE) according to specific cardiac events (CE) during follow-up. CHF = congestive heart failure; MI = myocardial infarction.

Sensitivity and specificity of predictive variables: The sensitivity, specificity and predictive accuracy for the scintigraphic variables, the exercise electrocardiogram, and a history of MI are shown in Table VIII. Overall, the change in LV ejection fraction, ESVI and P/V index were accurate in predicting prognosis, particularly at 6-month follow-up, by which time 9 additional patients had had cardiac events and had changed from having false- to true-positive results. The change in wall motion score was the next best indicator, with a sensitivity, specificity, and predictive accuracy of 79% at 6 months. The change in LV ejection fraction, ESVI, and P/V index were all significantly better in classifying patients than ST-segment changes during submaximal exercise, an LV ejection fraction <0.40 at rest and a history of MI (p <0.001). They were also better than changes in wall motion score (p <0.005). These same general relations were maintained even when the patients were grouped according to infarct distribution (Table VIII). In those patients who had no cardiac event after 6 months of follow-up, 37 of 43 (86%) had a normal response of both LV ejection fraction and ESVI to submaximal exercise, and 35 of these 37 patients had a normal P/V index response as well.

Discussion

This study demonstrates that submaximal exercise with RVG can be performed safely 2 to 3 weeks after MI, and that it is effective in identifying patients most and least likely to have cardiac events in the ensuing 6 months. These findings support our observations in 61 patients[18] and demonstrate that patients can be separated into 2 groups: 1 with a low probability of further cardiac events and 1 with a high probability of cardiac events. This prognostic separation of patients can be made irrespective of MI location and type.

After 6 months, 74 of the 117 study patients had cardiac events: 41 died or had a recurrent MI or medically refractory angina and 33 patients had persistent congestive heart failure or limiting angina. Between 3 and 6 months of follow-up, 2 patients who had not had cardiac events at 3-month follow-up and 13 patients who had minor cardiac events progressed to at least 1 major event. Each had abnormal scintigraphic evaluations initially.

Patients in this study continued receiving medical therapy during exercise testing and after discharge. Furthermore, an abnormal result was related to the responsible physician so that an effort could be made to optimize their management. This differs from most other studies of a similar patient population and may account for the relatively low incidence of death (8%) in our patients.[21,22,41]

Like many other centers performing equilibrium exercise RVG, our patients were exercised supine with a bicycle ergometer.[41,42] This differs from most other studies of this type, which are performed upright with a treadmill or bicycle ergometer.[21–25,27] Also, the Frank (X,Y,Z) lead system was used to monitor patients during exercise.[32] Blackburn[33] showed that the ST-segment vector of Frank leads are approximately half that of standard leads or a bipolar V_5.[33] When this information is taken into account, however, the sensitivities of the 2 systems are reported to be comparable.[34] Regardless, this may have contributed to the relatively poor sensitivity and specificity of the exercise electrocardiogram in this study.

Our patients were separated into groups according to MI distribution. As would be expected, patients with anterior transmural MI had a higher incidence of cardiac events ($p = 0.01$) than the other groups. They also may have had an increased incidence of diabetes mellitus ($p = 0.063$) and, as others have shown, the poorest LV function at rest and during exercise (Fig. 1).[4,5,8,10,26] The frequency of previous MI may have been increased in the extensive nontransmural group ($p = 0.055$). The limited nontransmural group was similar to the patients evaluated by Lown,[43] Rigo,[44] Mahoney,[45] and coworkers who had normal QRS complexes, that is, only ST and T-wave changes on the electrocardiogram and a "mild course" after discharge. Four patients in this group did have a previous MI and 2 had abnormal QRS complexes. One patient had lost previously significant Q waves in the inferior leads and 1 had a previous nontransmural MI. Although this group clearly had the best resting LV ejection fractions (Fig. 1), 8 of 18 had follow-up cardiac events, 5 of which were major. Three of the 4 patients with previous MIs, none of whom had resting LV ejection fractions of <0.40, had cardiac events. However, even if they were eliminated from the group, the incidence of cardiac events was not different from that in patients with inferior transmural and extensive nontransmural MIs. The extensive nontransmural group had significantly larger LV volumes and poorer LV function, similar to the patients in Rigo's "nontransmural-B" category.[44] Nevertheless, their prognosis was no worse than that for patients with limited nontransmural MIs.

TABLE VIII Sensitivity, Specificity, and Predictive Accuracy of Radionuclide Ventriculographic, Electrocardiographic, and Clinical Variables for Predicting Follow-Up Cardiac Events at 6 Months Follow-Up: All Patients and Individual Infarct Groups

	All Patients (n = 114)			Anterior TM (n = 33)			Inferior TM (n = 39)			Limited NT (n = 18)			Extensive NT (n = 24)

Acc = predictive accuracy; ESVI = left ventricular end-systolic volume index; LVEF = left ventricular ejection fraction; MI = myocardial infarction; NT = nontransmural; P/V index = systolic blood pressure/left ventricular end-systolic volume index; Sen = sensitivity; Spec = specificity; ST↓ = ST-segment depression.

Only Pulido,[26] Borer,[41] Corbett,[18] and their coworkers have reported evaluations of the usefulness of submaximal exercise and RVG in patients after MI. Borer et al found little difference in resting ventricular function between the different MI groups even when patients with first MIs were compared. Further, he found little variation in LV ejection fraction with submaximal exercise and felt that it was of no additional help in identifying patients who died, all of whom had resting LV ejection fractions <0.35. We found, as did Pulido et al, significant differences in resting LV function with different MI distributions (Fig. 1) even when patients are separated according to the presence or absence of follow-up cardiac events (Fig. 2). The patients with follow-up cardiac events in this study had significantly lower resting LV ejection fractions and P/V indexes and larger LV volumes. Although 26 of 29 patients with resting LV ejection fractions <0.40 had cardiac events, 48 of 88 (55%) patients with resting LV ejection fractions ≥0.40 also had cardiac events.

Our data emphasize that the change in LV ejection fraction and end-systolic volume index with submaximal exercise are the best predictors of cardiac events during the subsequent 6 month follow-up.[18] Except for patients with anterior transmural MIs, these scintigraphic parameters were entered first by the stepwise multivariate discriminant analysis (Table VI), and were consistently ranked first and second in the initial step. They had the best sensitivities, specificities and predictive accuracies independent of MI distribution (Table VIII). The LV P/V index was consistently the third highest rated variable in the first step of the discriminant analysis. Most of the patients in the present study had significant changes in LV function with exercise. Thirty-nine of 41 patients without cardiac events had an increase in LV ejection fraction of ≥0.05 and 56 of 74 patients with cardiac events had a decrease in LV ejection fraction with submaximal exercise, 44 by >0.05. The discriminant function was less successful in classifying patients into "no cardiac event," "minor cardiac event" and "major cardiac event" groups than simply into event and no-event groups. This is similar to the findings in our preliminary report in fewer patients.[18]

The patients with anterior transmural MI were found by the discriminant function to have their prognosis predicted best by the peak submaximal exercise LV ejection fraction (Table VII). This was also the case when only patients with LV ejection fractions <0.40 were analyzed. However, these 2 groups were not entirely comparable; only 13 of 33 patients with anterior transmural MIs had resting LV ejection fractions <0.40. Despite these differences, the peak submaximal exercise LV ejection fractions appeared to provide the most prognostic information in the patients with the most severe LV dysfunction.

Most previous studies of prognosis after MI were performed before the general availability of scintigraphic techniques for the evaluation of ischemic heart disease.[3,4,22,43] Because of this, previous exercise studies have relied almost exclusively on the electrocardiogram and other noninvasive hemodynamic measurements.[21–25] We also found electrocardiographic S segment depression to be predictive of cardiac even (Table III). However, the predictive accuracy of th variable was only 61%, significantly less than the chan with submaximal exercise in LV ejection fractio end-systolic volume index and the LV P/V index <0.001). Recently, submaximal exercise and thalliur 201 scintigraphy were used in 2 studies to detect th presence of multivessel coronary artery disease after M and predicted 83 and 63%, respectively, of stenose vessels supplying myocardium at risk.[46,47] Neither these studies specifically addressed follow-up prognosi Silverman et al[17] used a quantitative assessment thallium-201 defect size to predict longer-term pro nosis. A large defect was predictive of follow-up mo tality.[17]

In summary, this study confirms that submaxim exercise RVG performed before hospital discharge aft MI is usually safe, convenient, and helpful in the ide tification of those patients at risk for further cardi events. This capability exists independently of MI l cation and the degree of LV dysfunction at rest ar applies to patients with either transmural and no transmural MI.

Intracoronary Thrombolysis in Acute Myocardial Infarction

WILLIAM GANZ, MD

Forty-seven patients with acute myocardial infarction (MI) underwent intracoronary infusion of Thrombolysin® or streptokinase. In 41, a completely reoccluded artery was reopened. Patency was associated with appearance of arrhythmias, relief of pain, gradual return of the ST-segment to the baseline and appearance of abnormal Q waves. Creatine kinase (CK) and MB-CK enzyme levels peaked earlier. Serial thallium scintigrams showed reduction in defect size after reperfusion, and the ejection fraction was higher compared with control. Eighteen patients were recommended for coronary bypass surgery for recurrent pain or severe multivessel disease.

Massive necrosis remains the principal cause of death and morbidity among patients hospitalized with acute myocardial infarction (MI). Extensive infarcts induce heart failure, cardiogenic shock and malignant dysrhythmias. Interventions designed to minimize myocardial necrosis by reduction of myocardial oxygen demand, augmentation of collateral blood supply and correction of various ischemic cellular defects have not been sufficiently effective in patients with MI. It is becoming increasingly apparent that anterograde flow to the ischemic myocardium must be restored to salvage substantial quantities of jeopardized myocardium and to improve the prognosis of patients with MI.

Coronary Artery Reperfusion

Physiologic background: In dogs, myocardial necrosis may begin as early as 20 minutes after coronary artery occlusion and then progress in a wave front from the subendocardium toward the epicardium. The rate and extent of necrosis varies depending on the site of occlusion, the presence of collateral channels and on hemodynamic and metabolic variables that affect collateral blood flow and myocardial oxygen demand. In some dogs, transmural necrosis was observed after only 40 minutes of coronary artery occlusion; in others, little necrosis was present after 3 to 6 hours of occlusion. In most dogs and monkeys, the process of necrosis is practically complete after 6 hours of coronary artery occlusion.[1,2] The rate of necrosis in humans is affected by additional factors, such as the rate and completeness of coronary occlusion and the presence and extent of acquired collaterals. In patients with acute MI at highest risk, the ischemia is extensive and severe.[3] In such patients, the time limit for clinically meaningful reperfusion is probably substantially less than 6 hours. On the other hand, in patients with extensive collaterals or incomplete occlusion of the coronary artery, significant myocardial salvage is probably possible well beyond 6 hours.

Markers of reversible injury: Because of a wide variation in the time course of necrosis, the availability of markers of reversible or irreversible injury would be of great value for assessing the likelihood of significant myocardial salvage in a given patient.

The electrocardiogram: Isolated T-wave abnormalities suggest reversible myocardial ischemia, whereas ST deviations are consistent with both reversible and irreversible injury. Abnormal Q waves usually indicate myocardial necrosis. Experimental studies as well as clinical experience in patients with successful intracoronary thrombolysis, however, indicate that the development of electrocardiographic signs of necrosis often lags several hours behind the anatomic course of necrosis. Thus, the absence of Q waves and R-wave diminution in the first hours of an acute MI does not rule out that the injury is already irreversible.

Myocardial enzymes: Abnormally elevated activity of serum creatine kinase (CK) and other myocardial enzymes are, in general, considered indicative of myocardial necrosis. The enzyme molecules released from the irreversibly injured myocardial cells initially remain in the myocardium and are only slowly carried into the systemic circulation by the collateral blood circulation and the lymphatic vessels. It is not surprising, therefore, that animal studies as well as clinical experience in patients who underwent successful intracoronary thrombolysis indicate a significant time lag between the course of anatomic necrosis and the abnormal elevation of enzyme activity in the serum, since normal serum levels of myocardial enzymes in the first hours of an acute MI do not rule out the presence of extensive necrosis.

Regional wall motion abnormalities: The myocardium becomes dyskinetic seconds after occlusion of a coronary artery. Regional wall motion abnormalities

From the Division of Cardiology, Department of Medicine, Cedars-Sinai Medical Center, UCLA School of Medicine, Los Angeles, California. This study was supported in part by the Specialized Centers of Research Material Institutes of Health Grant 17651, and by the United Hostesses' Charities and the Hayton Foundation, Los Angeles, California.

are not helpful in differentiating reversible ischemia from irreversible injury in the early hours of an acute MI.

Coronary thrombosis: Numerous studies in recent years have confirmed that thrombosis is usually the mechanism of coronary artery occlusion in transmural MI. The frequency of thrombotic occlusion in autopsy studies ranged from 88 to 97.5%.[4] In vivo angiography and retrieval of thrombi by the surgeon in most patients with acute MI undergoing coronary bypass operation support the postmortem findings. Thrombosis in the coronary artery is triggered by rupture of an atherosclerotic plaque.[5] Experience in patients with acute MI undergoing nonsurgical reperfusion indicates that spasm, contrary to previous reports, is rarely, if ever, the cause of coronary artery occlusion.

Coronary thrombolysis in acute myocardial infarction: Multicenter trials were conducted to determine whether lysis of the coronary artery thrombus would reduce mortality in patients with acute MI. These studies used intravenous streptokinase or urokinase.[6] The initial trials indicated a reduction in mortality; later studies conducted under more rigorously controlled conditions failed to confirm the early findings. A recent study conducted in Europe[7] reported a reduction in mortality. The main weakness of these studies was that treatment was begun too late to seriously reduce myocardial damage. Experimental evidence suggests that systemic thrombolysis is slow and unreliable. Clinical studies are being conducted in which streptokinase is administered early and its effect on coronary patency is assessed by angiography. These studies should determine the role of systemic thrombolysis in the management of acute MI.

Intracoronary thrombolysis: Experimental studies in our laboratory and elsewhere demonstrated that intracoronary thrombi can be lysed rapidly (within minutes) by local application of thrombolytic agents. In vivo and in vitro studies using a mixture of streptokinase and plasminogen (Thrombolysin®) also showed that the rapidity of thrombolysis increases with the concentration of the thrombolytic agent at the clot. Histologic study of the coronary artery and the myocardium exposed to several hours of Thrombolysin infusion revealed no toxic effects attributable to the infusion.

Relevance of intramyocardial bleeding after coronary reperfusion: It was suggested previously[8] that reperfusion of an occluded coronary artery might be detrimental in that it could produce intramyocardial hemorrhage. However, labeling of microvascular damage with colloidal carbon proved that intramyocardial hemorrhage after reperfusion is the consequence of ischemic microvascular injury present before reperfusion and found in areas of most advanced myocardial necrosis, predominantly in the subendocardium.[8]

Mechanical function after reperfusion: The mechanical function of the reperfused myocardial region usually remains markedly depressed. Although during coronary occlusion the ischemic myocardium cannot increase its contractile function in response to inotropic stimulation, after reperfusion the depressed mechanical function of the previously ischemic myocardium can be substantially improved by inotropic stimulation. These findings suggest that intractable heart failure caused by extensive myocardial ischemia and unresponsive to inotropic stimulation could be successfully treated by early reperfusion and inotropic enhancement.

Clinical studies: Patients with evolving myocardial infarction likely to benefit from reperfusion of the occluded coronary artery are candidates for intracoronary thrombolysis. The following criteria are used for patient selection. The patient is seen within 3 hours of the onset of chest pain; the pain is not relieved by nitroglycerin; the electrocardiogram manifests ST-segment elevation ≥3 mm with reciprocal ST depression; there is no contraindication to anticoagulation; the patient consents to the procedure or the patient's relatives and the patient's primary physician consent to it.

In the catheterization laboratory, an indwelling Longdwell Teflon™ needle is placed in the left femoral artery for arterial pressure, monitoring, and blood sampling. An 8F Judkins angiography catheter is inserted into the right femoral artery. A 2,500-IU bolus of heparin is administered intravenously. In patients with anteroseptal infarction, the right coronary artery is visualized in a single view. In patients with inferior infarction, the left coronary artery is visualized first, because the right coronary artery is more likely to be the site of occlusion. Nitroglycerin, 0.1 mg in 2 ml of 5% dextrose, is injected slowly into the occluded coronary to rule out that the occlusion is caused by spasm. Heparin, 5,000 IU, is added intravenously.

For infusion of the thrombolytic agent, a special radiopaque catheter (coronary infusion catheter, American Edwards Laboratories) 2.5F in diameter is inserted through the lumen of the angiography catheter. The distal 20-cm segment of the catheter is reduced to a 2F diameter, and is very soft and flexible to prevent mechanical damage to the coronary artery. To facilitate precise location, the tip is made strongly radiopaque so that it can be seen inside the angiographic catheter. The infusion catheter is advanced to the site of occlusion. The propriety of catheter position is checked in at least 2 views. The infusion catheter is slightly stretched to eliminate redundancy and to prevent the catheter from moving downstream when the artery becomes partially patent. During infusion of the thrombolytic agent, the angiography catheter remains in the ostium of the coronary artery. The space between lumen of the angiographic and the infusion catheter allows continuous monitoring of the intracoronary pressure and intermittent injection of contrast material to check whether the artery is patent, without interrupting the treatment. Streptokinase is injected at a rate of 2,000 IU in 1 ml of saline/min, until arterial patency is achieved, but no longer than 100 minutes. When the artery is reopened, the infusion is reduced to 1,000 IU/min and maintained for an additional 60 minutes. The protracted infusion is necessary because at the time of initial patency the clot is usually not completely lysed; discontinuation of thrombolysis at that point could result in regrowth of the thrombus and reocclusion.

After termination of the thrombolysis, coronary angiography is completed and left ventriculography is

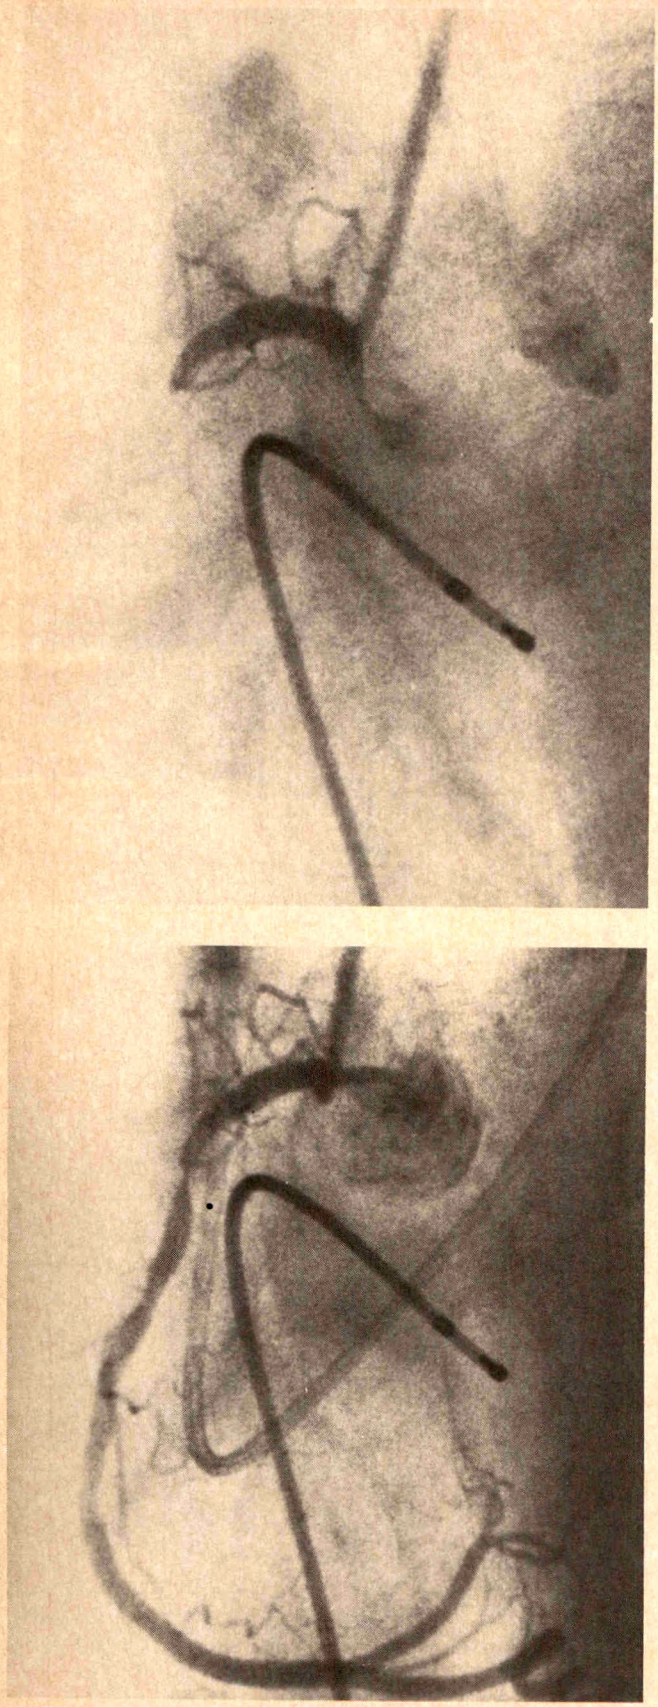

FIGURE 1. Angiograms of the right coronary artery in a patient admitted after 1 hour of chest pain with electrocardiographic signs of an acute inferoposterolateral infarction. **Top,** Before intracoronary thrombolysis. **Bottom,** At the completion of the procedure. The patient received a total of 300,000 IU of Thrombolysin® in 75 minutes.

performed. After the procedure, the patient is tran ferred to the cardiac intensive care unit. When th partial thromboplastin time returns to below twi control, the angiography catheter is removed from th groin. After hemostasis, an infusion of heparin is in mediately begun at a rate of 800 to 1,000 IU/h to mai tain partial thromboplastin time between 1.5 and times control. After several days, warfarin is substitute for heparin and maintained for 3 months. Anticoag lation is limited to 3 months on the assumption tha thrombosis of the coronary artery was triggered by defect in the endothelium secondary to rupture of th plaque, and that the defect will be healed and becom nonthrombogenic during this period.

Intracoronary infusion of Thrombolysin or strep tokinase resulted in reopening of the completely oc cluded artery in 41 to 47 patients (Fig. 1). The lumen a the completion of Thrombolysin infusion was usuall larger than at the time of initial patency, suggestin further lysis of the clot. In 3 of 5 patients who wer restudied 10 to 14 days after thrombolysis, the lume size further increased, suggesting either further lysis c the clot or shrinkage of the underlying atherosclerot plaque; in 2 patients there was no appreciable chang in lumen size.

Patency was frequently signaled by the appearanc of ventricular dysrhythmias like premature ventricula complexes, bigeminy or isorhythmic dissociation. Tw patients had ventricular tachycardia and 1 ventricula fibrillation; all 3 responded to electrical conversion Patency was followed by relief of pain, gradual retur of the ST segments to the baseline and, frequently, b development of abnormal Q waves, indicating that som necrosis had occurred before reperfusion. Atrioven tricular and intraventricular conduction abnormalitie due to the recent coronary artery occlusion disappeare immediately after reopening of the artery. All of ou patients had normal serum CK and MB-CK levels be fore reperfusion. The enzymes began to increase im mediately after reperfusion and reached a peak 6 to 1 hours earlier than in the absence of reperfusion. Ex perimental studies suggest that the enzyme peak i about twice as high for the same amount of necroti myocardium than in the absence of reperfusion.

In 18 patients, elective surgery was recommende because of severe multiple vessel involvement or re current angina. The operation was generally well tol erated.

Thallium-201 scintigraphy was performed befor thrombolysis after intravenous injection of about 2 mC of the isotope and after intracoronary injection of 25 t 35 μCi of thallium-201 about 1 hour after reopening th artery and 10 days later after a second intravenou dose.[9] The scintigrams demonstrated significant re ductions in defect size after reperfusion in almost al patients, and virtually complete restoration in some. I our control patients with total coronary artery occlusion the defect size showed no change in the late study Studies of global and regional left and right ventricula function using multiple-gated blood pool scintigraph showed significantly higher ejection fractions after re perfusion than in the control group of patients withou

coronary reperfusion. Wall motion and global function showed further improvement 10 to 14 days after reperfusion. Similar results were reported from other centers.[10–14]

Perspectives

Intracoronary thrombolysis appears to be a relatively safe and effective way of reopening the occluded coronary artery in patients with evolving myocardial infarction. The clinical results are promising, notwithstanding that reperfusion is performed relatively late—3 to 5 hours after the onset of infarct symptoms. The results should significantly improve with earlier hospitalization and by administration of drugs that slow necrosis in the period preceding the reperfusion.

Coronary Artery Surgery in Australia

Report from the Committee of the National Heart Foundation Coronary Artery Surgery Register

DOUGLAS K. BAIRD, BSc (Med), MB, BS, FRACS, FACF, FACCP

Clinical data on all patients who have undergone coronary artery surgery in Australia are collected, audited, and published each year by the National Heart Foundation of Australia. These data from 1971 to 1980 are summarized and show the indications for operation, the variation in numbers of patien operated on in each state and unit, and the over increase in number of operations during t decade.

Australia is a country of 15 million people spread out over a continent approximately the size of the United States. Most of the population lives in large coastal cities, Sydney and Melbourne. As in many Western nations, coronary artery disease is the leading cause of death and is responsible for much disability and suffering.

Australia has 9 cardiac surgical units with 40 surgeons attached to them. Coronary artery surgery was first performed in 1970 and is now the most frequently performed major surgical procedure in this country.

The National Heart Foundation of Australia is an organization devoted to the education and research aspects in heart disease. As a national body it advises the government and community on cardiac disease. The Foundation has maintained a register of all open heart surgery since it began in Australia in the mid-1950s. Because of the medical, sociologic and economic implications of coronary artery surgery, a register of all patients operated on in Australia was established by the National Heart Foundation. Individual units complete clinical details of patients operated on and forward these to the National Heart Foundation headquarters in Canberra, where the data are processed and entered on computer. An audit is done and a report is published each year regarding all patients who have had coronary artery surgery in Australia.

The register is maintained by the staff of the National Heart Foundation. The results are reviewed by a vol-

untary committee consisting of cardiac surgeons and cardiologists. The data come from all patients operated on for coronary artery disease in Australia plus their short-term outcome. Subsets of particular interest can be analyzed. No follow-up data are available.

The number of patients operated on from 1971 through 1980 and the decrease in mortality over this decade are listed in Table I. In 1980, >4,000 patients were operated on, with an operative mortality rate of 1.8%. All patients who had other procedures, such as valve replacement or coronary revascularization, are included. The number of grafts per patient has increased over the years and reflects common practice elsewhere in more complete revascularization (Fig. 1).

The number of operations for each of the 9 units in 1980 is shown in Table II. All but the first unit shown are in major teaching hospitals.

Australia is a commonwealth of 6 independent sovereign states, each with its own health service, medical education facilities, and specialist referral hospitals. Table III shows marked variation in the incidence of coronary artery surgery between the states. The rates are expressed as operations per million of population in 1974 and 1980. The number of patients operated on has increased markedly over 6 years, but the average

figure in 1980 was 234 per million. This rate is less than that of the United States—approximately 550 cases per million.

The indications for operation in 1980 are detailed in Table IV. Most patients were operated on for chronic stable angina. Operation on asymptomatic patients or for prognostic reasons was uncommon, about 1 in 200 patients. Reoperations for recurrent coronary artery disease accounted for 1.5% of the total.

Table V shows the ratio of patients with stable versus unstable angina operated on in each state and illustrates that medical and surgical practice varies in each state.

The severity of coronary disease in patients in 1980 is shown in Table VI. (Significant disease is defined as >70% vessel obstruction.) Seven percent were operated on for 1-vessel disease, 18% for 2-vessel disease, 57% for 3-vessel disease, and 18% for >50% left main disease. The operative mortality rate increases from 1-vessel to left main disease.

Table VII shows the number of grafts placed pe patient and th r respective mortality rates in 1980. Th reflects the ommon finding that the number of graf and the extent of additional procedures is usually re lated to mortality, except for valve replacement, whe coronary artery disease is often incidentally found a angiography.

The mortality rate by age and sex with revascula ization only and with the other procedures is shown i Table VIII. The mortality rate increases with ag women aged >60 years who have additional procedure have a higher mortality rate.

Overall, the indications for surgery and the results i Australia do not differ widely from those of othe Western nations. The Coronary Artery Surgical Reg ister of The National Heart Foundation is unique however, in that the number and distribution of a patients in the country who are operated on for coronar disease are known, and therefore, annual trends c changes in practice and mortality can be assessed.

Calcium-Entry Blockers and Cardiovascular Disease

PAUL M. VANHOUTTE, MD, and RICHARD A. COHEN, MD

The beneficial effects of calcium-entry blockers in the treatment of ischemia in the heart and in other tissues can be explained by (1) relaxation of venous smooth muscle, in particular that of the splanchnic veins; (2) negative inotropic effect on the myocardial cells; (3) negative chronotropic effects on the heart; (4) inhibition of vasospastic episodes in coronary and other large arteries; (5) depression of myogenic activity and responsiveness to vasconstrictor stimuli in precapillary resistance vessels; (6) inhibition of platelet aggregation; (7) possible increases in the deformability of hypoxic red blood cells; (8) protection of endothelial integrity and function; and (9) protection of the body cells, in particular myocardial cells, from prolonged exposure to anoxia and from massive entry of calcium during reperfusion. In the case of angina pectoris, the effects on the myocardial cells themselves, the decrease in preload and afterload, and the improvement of coronary perfusion combine to allow the heart to perform more work before an imbalance is reached between the metabolic demands of the myocardial cells and their blood supply. The increased myocardial performance may favor collateral circulation and withdrawal of the reflex load upon the heart, originating from the ischemic myocardium. The available calcium-entry blockers vary in their potency to affect the different components of the cardiovascular system.

To ensure cellular life, there must be a continuous stream of nutrients from the outside world to the extracellular space and a continuous stream of waste products from the cells to the outside world. This is achieved by the blood and the cardiovascular system, whereby the different components contribute to the functioning of the whole. The behavior of each component is influenced by events both upstream and downstream from it.[1] Whenever the cardiovascular system fails to meet the demands of an individual tissue, cellular intoxication with resultant depression of tissue function occurs. Stimulation of sensory nerves becomes unavoidable (Fig. 1); this results in ischemic pain and may trigger autonomic reflexes which further tax the system (Fig. 2). The pathophysiologic causes and consequences of ischemia are remarkably similar in different tissues (for example, heart, brain, limbs), but the resultant clinical picture depends on the specific function of each tissue. Thus, myocardial ischemia is particularly dramatic hemodynamically because of the central role played by the heart in providing the energy required to move the blood around the vascular tree to all the other tissues of the body. In most, if not all of the components of the cardiovascular system, calcium ions profoundly modulate cellular function. The pharmacologic actions of calcium-entry blockers permit us to understand why these substances may help restore the balance between the oxygen demands of and the blood supply to ischemic tissues and allow one to predict their beneficial effects in the treatment of cardiovascular disease.[2–16]

Myocardial Ischemia

The beneficial effects of calcium-entry blockers in the treatment of angina pectoris[17,18] can be explained pharmacodynamically by the reduction in the amount of cardiac work or the improvement in perfusion of ischemic areas of the myocardium or both (Fig. 3). It is impossible to dissociate the actions of these drugs on the myocardium from those on vascular smooth muscle of the coronary and peripheral blood vessels.[2–4]

Work of the heart: The calcium-entry blockers can reduce cardiac work by:

(1) *Reducing the ventricular load.* By causing dilatation of the systemic veins, the calcium-entry blockers could reduce the *preload* of the ventricles.[1,19,20] To judge from the data available on isolated animal veins, these substances will affect mainly the splanchnic veins, which are a dynamic controller of the return of blood to the right atrium. Cutaneous veins appear to be less sensitive, which should ensure little interference by the calcium-entry blockers with the thermoregulatory and

orthostatic adjustments of the peripheral venous system.[6,7,14,15]

By inhibiting the myogenic tone of the precapillary vessels and decreasing their responsiveness to vasoconstrictor substances, the calcium-entry blockers reduce 1 of the major dynamic determinants of circulatory impedence, the systemic vascular resistance, and thus the afterload of the left ventricle.[1,21–23] These effects are most pronounced for substances such as verapamil and nifedepine, which explains their potential use as antihypertensive agents.[14]

Exaggerated entry of calcium into ischemic myocar dium may result in a slower rate of ventricular relaxa tion, resulting in an increased end-diastolic ventricula pressure[24]; by increasing the rate of relaxation, th calcium-entry blockers could decrease the load on th ventricular wall.

(2) *Decreasing myocardial contractility.* In vitro, a calcium-entry blockers have a negative inotropic effec

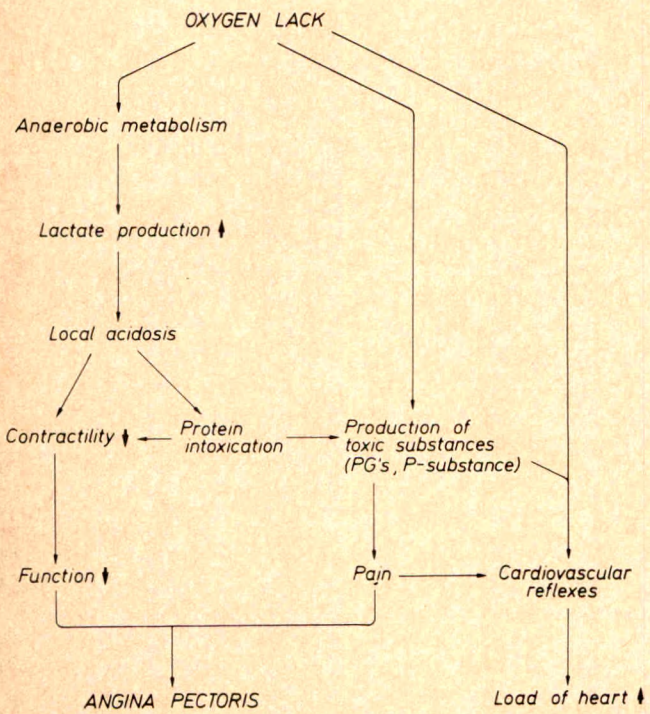

FIGURE 1. The consequences of tissue ischemia. The myocardium is taken as an example, but similar events occur in other tissues, such as skeletal muscle, leading to the combination of decreased function and pain perception (intermittent claudication). however, important differences exist between the individual compounds in terms of their potency to decrease myocardial contractility versus their ability to inhibit vasoconstrictor responses of isolated blood vessels, in particular coronary arteries.[6,8,11,25–28] Thus, with compounds such as lidoflazine, myocardial depression is not observed in clinically effective doses.[16] Furthermore, in the intact organism, the negative inotropic effect of calcium-entry blockers can be counteracted by the reflex increase in sympathetic drive to the heart caused by reductions in systemic vascular resistance (e.g., nifedepine).[17,29]

Decreases in myocardial contractility undoubtedly reduce the imbalance between metabolic demands and oxygen supply in the heart, and thus can alleviate the symptoms of angina pectoris. However, this is attained at the cost of reducing the maximal potential of the heart to perfuse peripheral tissues at times of increased demands, and thus might limit muscular exercise.

(3) *Decreasing heart rate.* The negative chronotropic properties of the calcium-entry blockers vary, depending on their propensity to depress the generation and conduction of impulses in the specialized tissues of the heart, the reflex adjustment of sympathetic tone they induce, and their potency in inhibiting the release of the adrenergic transmitter by the adrenergic nerve terminals.[30] Clinical doses of some calcium-channel blockers decrease heart rate at intermediate work loads without affecting the maximal heart rate that can be achieved or myocardial contractility; higher values of cardiac output can be achieved at maximal loads.[11,12,28,30]

Coronary perfusion: Provided their effect on diastolic pressure is not marked, the calcium-entry blockers can theoretically improve coronary perfusion to the ischemic areas of the heart by:

(1) *Decreasing heart rate.* A reduction in heart rate at rest and during submaximal levels of exercise will prolong the diastolic filling time of the coronary circuit.[12]

(2) *Reducing wall tension.* A decrease in ventricular wall tension, whether due to improved relaxation of the myocardium or to a decreased external load (see section on "Work of the heart") will decrease the mechanical compression of the coronary microvessels, and thus improve coronary perfusion.

This may be particularly important in anoxic regions where calcium-entry blockers prevent the rigor of the myocardial cells due to exaggerated accumulation of intracellular calcium[28,31] and explain the redistribution of blood flow they cause from normally perfused to ischemic areas.[12,32,33]

(3) *Dilating coronary resistance vessels.* The calcium-entry blockers have a direct inhibitory effect on coronary vascular smooth muscle, and increase coronary blood flow at rest in the animal and in patients with angina pectoris.[22,25,26] In addition, compounds such as lidoflazine delay the breakdown of the endogenous coronary vasodilator adenosine.[8,12,14] The question of importance is whether or not the ability of the coronary resistance vessels to dilate is curtailed or if coronary arterioles are constricted to a greater degree than normal in ischemic regions of the heart. The calcium-entry blockers would have to preferentially vasodilate the ischemic regions to avoid a circulatory steal phenomenon toward the areas of the heart.[1,33] The data available on isolated coronary arteries suggest that conditions mimicking tissue ischemia, particularly the combination of a very low oxygen partial pressure, with high extracellular concentrations of potassium, cause profound constrictions of coronary vascular smooth muscle, and that these constrictions can be inhibited by calcium-entry blockers.[12–15]

(4) *Antagonizing coronary vasospasm.* In some patients with angina pectoris, spastic constriction of the large coronary arteries may be the primary cause of the myocardial ischemia (Prinzmetal's angina, variant angina), or may exacerbate the blood flow restriction due to a partial atherosclerotic obstruction of the coronary lumen.[17,34,35] Although the cause of such coronary spasm is unknown, the clinical evidence that calcium-entry blockers can prevent it is convincing. Nifedipine prevents an abnormal coronary vasoconstriction in response to the cold pressor test in patients with coronary artery disease who are taking propranolol.[36] In vitro work on large animal coronary arteries demonstrates that these compounds inhibit constrictions caused by several possible mediators of coronary vasospasm or by ergonovine maleate, which is used diagnostically to induce coronary spasm.[8,12–14]

(5) *Augmentation of collateral flow.* Data from animals suggest that calcium-entry blockers such as lidoflazine and diltiazem accelerate the normally occurring phenomenon of collateralization; this improvement of collateral formation is probably a consequence rather than a cause of the improved cardiac function and of the resulting ability to increase physical activity.[12,33,37]

The net result of treatment with a given calcium-entry blocker will also depend on the time course of action of the drug. Thus, agents with acute and pronounced vasodilator properties in systemic arterioles and veins (e.g., nifedepine) will cause an almost instantaneous unloading of the heart, similar to that obtained with nitrates. With more slowly acting drugs (e.g., lidoflazine), the immediate hemodynamic effects of clinical doses may not be so obvious. However, as the condition of the ischemic myocardium improves over time, diseased cells regenerate and can perform more work. The reflex vasoconstriction (Fig. 2) originating in the ischemic myocardium decreases, and more of the improved energy-generating potential of the heart can be used to meet the demands of metabolically active tissues.

Other Tissues

Provided the pressure generated by the heart is maintained at an appropriate level, the amount of blood delivered to each tissue will depend on the resistance flow it offers, and thus mainly upon the diameter of its blood vessels and the viscosity of the blood. In normal conditions, the degree of opening of the arterioles is governed by the metabolic needs of the tissues surrounding them, which ensures an appropriate blood supply.[1,38,39] There is no evidence that in abnormal

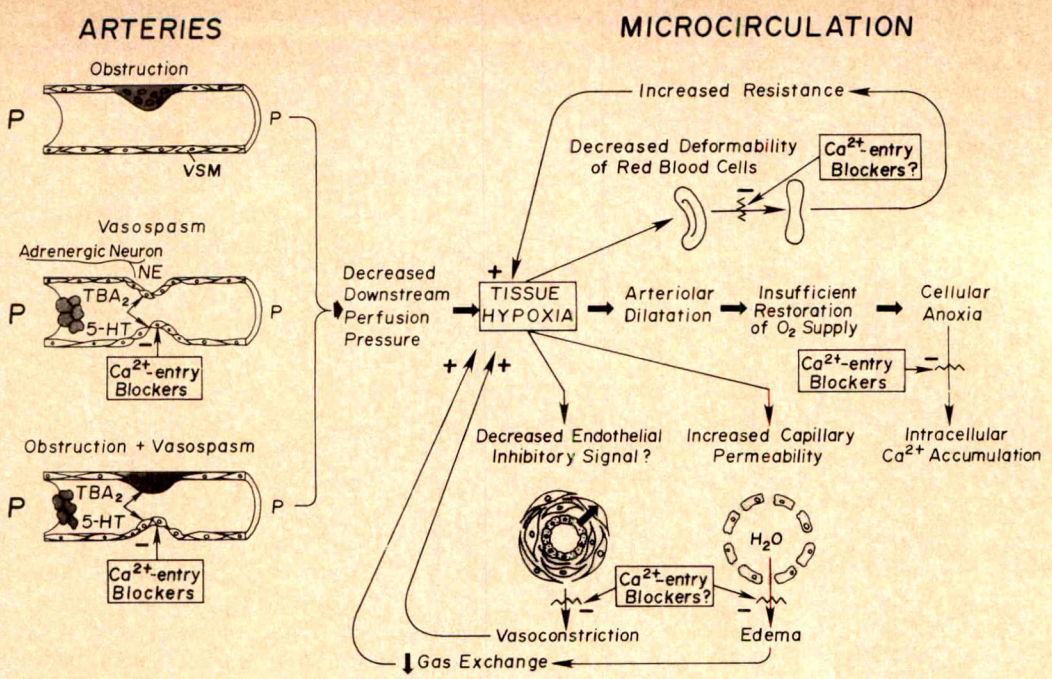

FIGURE 4. The events leading to and maintaining tissue ischemia, with indication of the possible sites of action of calcium-entry blockers. P = blood pressure; VSM = vascular smooth muscle; 5-HT = 5-hydroxytryptamine. Reprinted from Vanhoutte[5] with permission of the publisher.

conditions the precapillary resistance vessels lose the ability to dilate in response to the metabolic demands of the tissues that they subserve. However, in certain forms of arterial hypertension, an arteriolar constriction may contribute to the origin or the maintenance of the disease; in those cases, calcium-entry blockers, particularly those that affect the myogenic activity of vascular smooth muscle most, have antihypertensive properties.[14] Ischemia of peripheral tissues, including the brain, occurs mainly when the diameter of a large artery is reduced and if the collateral circulation is insufficient to meet the demands of the active tissue. If the restriction of the blood flow to an organ is due solely to mechanical obstruction (for example, atherosclerosis, embolism, external compression), no primary beneficial effect is to be expected from calcium-entry blockers, or from other types of vasodilator drugs; in contrast, vasodilator treatment may result in further restriction of the blood flow to the ischemic tissues because the drugs cause a decrease in resistance in normally oxygenated beds (steal phenomenon).[1,40]

However, obstruction can be due to spasm of the vascular smooth muscle of the arterial wall, as may be the case in cerebral arteries in migraine headache or in digital arteries during episodes of Raynaud's phenomenon. Other arteries also contain substantial amounts of vascular smooth muscle cells and, at least in vitro, react strongly to vasoconstrictor substances.[13,14,16,41] In all arterial smooth muscle studied so far, calcium-entry blockers have been shown to be potent inhibitors of the contractile responses evoked by a variety of vasoconstrictor substances; thus, one can predict that they will be effective in antagonizing arterial vasospasm not only in the coronary circulation (see "Coronary perfusion"), but also in other vascular beds.[2–5,13,14,42–44]

Another dynamic determinant of the resistance to flow is the viscosity of the blood; hyperviscosity has been proposed as 1 factor in peripheral circulatory disturbances. The viscosity of the blood is determined in part by the deformability of the red blood cells; this deformability is of critical importance at the microcirculatory level, where the erythrocytes must travel through capillaries with a diameter smaller than their own. Metabolic deprivation markedly reduces red blood cell deformability, which theoretically should increase the apparent viscosity of the blood in the precapillary vessels and, thus, the resistance to flow, and may further reduce proper oxygenation of the tissues.[1,13,45,46] Certain calcium-entry blockers can reduce the viscosity of hypoxic blood; this could explain, in part, a beneficial effect on peripheral vascular insufficiency,[45,46] although in vitro demonstration of such effects often requires suprapharmacologic concentrations.[46] Another possible reason for mechanical hindrance of blood flow at the microcirculatory level is the occurrence of platelet aggregates; certain calcium-entry blockers have strong antiaggregating properties[12] (Fig. 4).

In contrast to the heart, and with the exception of skeletal muscles engaged in isometric contractions, the tissue pressure in peripheral organs usually is not considered to be an important determinant of the resistance to flow at the microcirculatory level. Tissue pressure may limit blood flow in edematous tissues, where exaggerated extravasation of fluid occurs when capillary permeability increases. It has been suggested that such

increased permeability may be caused by the contraction of actomyosin-like proteins in the endothelial cells, which widens the pores of the capillary membrane; contraction of the endothelial cells facilitates their desquamation and their appearance in the peripheral blood.[47] Certain calcium-entry blockers have long been known to decrease peripheral edema formation,[12] and the calcium-entry blockers tested so far reduce the number of circulating endothelial cells.[47]

Conclusion

Most of the proposed therapeutic effects of calcium-entry blockers in cardiovascular disease can be related to their effects on the function of the contractile cells located in the heart and the vascular wall; their effects on the formed elements of the blood are still a matter of discussion. It should be emphasized that even if the direct interference of calcium-entry blockers with the contractile process in cardiac and vascular muscle cells fails to restore an appropriate blood flow to ischemic areas, these substances will prevent exaggerated influx of extracellular calcium during and after the ischemic episodes, and thus protect the tissue cells against some of the most deleterious effects of oxygen deprivation and the most damaging events in the early stages of reperfusion. Although this has been documented best in the myocardium,[28,31] it can be expected that a similar protective effect against anoxia can be obtained in other tissues (e.g., brain) as well. Finally, the reduction in the degree of desquamation of the endothelial cells observed with most calcium-entry blockers, and the inhibition of platelet aggregation caused by some of them, should not only reduce the release of vasoconstrictor substances (such as 5-hydroxytryptamine or thromboxane A_2, which may be a factor in arterial vasospams) from platelets aggregating at endothelial lesions, but may also slow the progression of the atherosclerotic process in both coronary and systemic arteries.[1,48,49] In that regard, it is interesting to note that the calcium antagonist lanthanum prevents atherosclerosis in animal models of the disease.[50]

Beta-Adrenoceptor–Blocking Drugs: Current Status and the Significance of Partial Agonist Activity

WILLIAM J. LOUIS, MD, FRACP, JOHN J. McNEIL, PhD, FRACP,
BEVIN JARROTT, PhD, B Pharm, and OLAF H. DRUMMER, PhD, B App Sci

There is some evidence that partial agonism is an important property of beta-blocking drugs, and this property may be exploited to produce a new range of positive inotropic drugs. With the established beta-adrenoceptor–blocking drugs, the level of partial agonist activity is weak and the dose-response curve for this property is shallow. However, its absence appears to increase the likelihood of inducing bronchospasm and bradycardia, and drugs that lack intrinsic sympathomimetic activity appear more likely to be associated with rebound cardiac arrhythmias on cessation of treatment. The idea of a small level of hormone activity—in this case catecholamine activity—being necessary to maintain normal cardiac and perhaps bronchial function is not new. Minimal doses of steroids are essential to maintaining the inotropic action of cardiac muscle. There is now enough accumulated evidence to suggest that a minimal degree of beta-adrenoceptor stimulation is also important for normal bronchial and cardiac function, and its absence increases the incidence of bradycardia and the risks of bronchospasm and rebound arrhythmias.

The use of the terms alpha and beta adrenoceptors for describing catecholamine receptors is now generally accepted. Beta adrenoceptors occur in a variety of sites, including blood vessels, heart, brain and kidneys; drugs that act on these receptors can modify not only cardiovascular disorders such as angina, high blood pressure and the cardiac arrhythmias, but also diseases such as asthma, thyrotoxicosis and migraine.

There are at least 2 types of beta adrenoceptors, $beta_1$ and $beta_2$, and tissues vary in their receptor complement. For clinical purposes, it is reasonable to use the classification listed in Table I. However, tissues such as heart, which contain predominantly $beta_1$ adrenoceptors, also contain some $beta_2$ adrenoceptors; consequently, selectivity is not absolute.[1]

Structurally, the beta-blocking drugs are modifications of the beta-adrenoceptor stimulant isoprenaline. They consist of an isoprenaline-like side chain with a different aromatic nucleus. When isoprenaline attaches to the beta adrenoceptor on the membrane surface, a number of specific linkages are involved. Each linkage is actually a weak bond; these bonds are formed rapidly, but are also easily broken. The highly specific way in which isoprenaline attaches itself to the receptor results in maximal activation of the receptor, which is believed to be linked to adenylate cyclase.[2]

The attachment of the blocking drug to the receptor resembles that of isoprenaline, but there are important differences. The attachment to the receptor results in less or no activation of adenylate cyclase and prolonged occupation of the receptor results in blockade. The mechanism of the occupation is uncertain, but it is known that these compounds compete with isoprenaline and other beta agonists for the receptor.

Classification

Beta-adrenoceptor–blocking drugs differ in 3 clinically important respects: intrinsic sympathomimetic activity, cardiac selectivity and bioavailability. The

TABLE I Classification of Tissue Beta Adrenoceptors

Tissue	Type of Receptor
Heart	$Beta_1$
Lung	$Beta_2$
Peripheral blood vessel	$Beta_2$
Central nervous system	$Beta_1$,$beta_2$
Metabolic receptors	Usually $beta_2$, but many are unclassified

membrane-stabilizing properties of these compounds usually occur at doses greater than those used in clinical practice.[3] These drugs can be classified in 2 ways: in terms of their selectivity for beta-adrenoceptor subtypes and according to the degree of intrinsic sympathomimetic activity that they possess. The frequently used nonselective compounds include drugs without intrinsic sympathomimetic activity, such as propranolol, timolol, nadolol and labetalol. Labetalol can also block alpha adrenoceptors. Oxprenolol, alprenolol and pindolol are nonselective drugs that possess intrinsic sympathomimetic activity.

Cardioselective drugs without intrinsic sympathomimetic activity include metoprolol, atenolol and bevantolol. Practolol is cardioselective and has intrinsic sympathomimetic activity. Acebutolol has weak intrinsic sympathomimetic activity and is cardioselective in animals, but not in man.

Intrinsic sympathomimetic activity: Intrinsic sympathomimetic activity is a property that has, in the past, been somewhat neglected; however, interest has been rekindled by reports that drugs with this property are less likely to induce bronchospasm and have a lower incidence of adverse effects, such as Raynaud's phenomenon.[4,5] There have also been reports that rebound cardiac arrhythmias may follow abrupt withdrawal of beta-adrenoceptor blockers with weak or absent intrinsic sympathomimetic activity.[6,7]

The first beta-adrenoceptor–blocking drug, dichloro-isoprenaline, had potent intrinsic sympathomimetic activity and increased the resting heart rate.[8] Clearly, the greater the positive inotropic action, the more likely this is to occur. However, available beta-adrenoceptor–blocking drugs with intrinsic sympathomimetic activity, such as pindolol, oxprenolol, alprenolol and acebutolol, have much less stimulant activity (Table II). The dose-response curves for the partial agonist property of these drugs is shallow and the inotropic action so weak that the net effect in man is to prevent the extreme effects of beta-adrenoceptor blockade, rather than to produce a positive inotropic effect. Moreover, the property does not interfere with their potency as beta-adrenoceptor–blocking agents, as they are equally effective in blocking exercise-induced tachycardia[9]; it merely reduces the effects of negative inotropism on tissues such as heart and lung.[10–12]

Thus, under resting conditions, heart muscle is under sympathetic stimulation and the complete absence of sympathetic activity may, on occasion, lead to bradycardia, cardiac failure and conduction defects.[11] Similarly, the absence of sympathetic activity in the bronchi may increase the percentage of the population that develops bronchospasm and increase the likelihood of patients with asthma developing an exacerbation of symptoms.[4,13]

Positive inotropic drugs: A new range of compounds which are partial beta-adrenoceptor agonists with significant positive inotropic properties have become available for clinical trials in various forms of cardiac insufficiency. These drugs include the cardioselective agonist dobutamine and the partial agonists prenalterol and ICI-118,587.[14–16] Prenalterol and ICI-118, 587 are structurally similar to the beta-adrenoceptor–blocking agents and have 20 to 60% of the maximal inotropic effect of isoprenaline. However, at high doses their blocking properties become more prominent and prevent further stimulation of the heart.

TABLE II Relative Degree of Intrinsic Sympathomimetic Activity (ISA) of Several Frequently Used Beta-Adrenoceptor–Blocking Drugs

Drug	Relative Degree of ISA
Dichloroisoprenaline	+++
Pindolol	++
Oxprenolol	+
Alprenolol	+
Acebutalol	+
Practolol	+
Propranolol	0
Timolol	0
Metoprolol	0
Atenolol	0
Nadolol	0
Labetalol	0

In heart failure, safe, selective, positive inotropic drugs could well be of value in improving cardiac performance. In the conscious animal, such compounds produce little increase in heart rate, presumably because their administration is associated with some increase in vagal activity and their blocking properties reduce the incidence of arrhythmias. The present group of partial agonists can only be given parenterally, but it is expected that orally bioavailable drugs of this type will soon become available; the hope is that they will be safe and effective in patients with chronic cardiac failure.

It would seem, therefore, in designing a beta-adrenoceptor–blocking drug with or without partial agonist activity, that many options are available, ranging from no activation of the receptor to full activation of the receptor. When the degree of activation is small and comparable in amount to resting endogenous sympathetic activity, the term *intrinsic sympathomimetic activity* has been invoked. It is, however, merely one end of the spectrum of partial agonism.

Extracardiac adverse effects: The extracardiac adverse effects of beta-adrenoceptor–blocking drugs include bronchospasm, aggravation of chronic bronchitis, abnormal dreams, nightmares and Raynaud's phenomenon. Beta-adrenoceptor–blocking drugs also have the usual incidence of gastrointestinal adverse effects, weakness and tiredness. One difficulty in assessing the value of intrinsic sympathomimetic activity in modifying the incidence of such adverse effects is the lack of sufficiently large clinical trials that compare drugs with and without this property. A similar problem affects the assessment of the value of cardioselectivity. Overall, the frequency of most extracardiac adverse effects is similar to that produced by nonselective agents. This suggests either that the current drugs are not very selective or that $beta_1$ adrenoceptors are widely distributed through the body.

Bronchospasm: Shortly after its introduction, it was found that propranolol could cause severe bronchospasm in asthmatic patients.[7] Stimulation of $beta_2$-adrenoceptors in normal bronchi leads to smooth muscle relaxation, and reduction in adrenoceptor activity seems to aggravate asthma and may even induce asthma in some patients with little or no history of chronic respiratory problems. There is some evidence in both animals and humans to suggest that drugs that lack intrinsic sympathomimetic activity are more likely to precipitate these asthmatic problems. Oh et al[18] have demonstrated that during an exercise challenge, patients pretreated with propranolol have greater airway obstruction than patients treated with pindolol or oxprenolol.

In comparative clinical trials, Morgan et al.[4] have reported a higher incidence of bronchospasm during treatment with propranolol and timolol, which lack intrinsic sympathomimetic activity, than during treatment with pindolol and alprenolol, which possess intrinsic sympathomimetic activity. In other studies,[19] patients whose lung function deteriorated with propranolol showed no deterioration with pindolol during acute and chronic treatment. There is considerable evidence that the cardioselectivity of drugs such as practolol, atenolol and metoprolol is only relative and may be lost at higher therapeutic doses.[20] If a patient does develop bronchospasm with a beta-adrenoceptor–blocking drug, however, there is evidence to suggest that $beta_2$-adrenoceptor agonists more easily reverse the bronchospasm during treatment with a cardioselective agent.[20,21] However, because all of these drugs are competitive antagonists, larger doses of salbutamol will reverse the bronchospasm induced by the more potent nonselective agents.[22]

These data should not be taken to mean that it is safe to use any of these particular groups of drugs in known asthmatic patients. All beta-adrenoceptor drugs, including the present range of cardioselective beta antagonists, can precipitate severe bronchospasm (sometimes fatal) in asthmatics and can interfere with the drug treatment of asthma.[23]

Given the widespread use of this class of drug, what is of concern is the precipitation of bronchospasm in patients without a clear-cut history of asthma. Although most patients show no deterioration in lung function during treatment with beta-adrenoceptor–blocking drugs, patients with no history of asthma have developed bronchospasm when they take drugs without intrinsic sympathomimetic activity; that is, the absence of sympathomimetic activity seems to increase the risk of bronchospasm. These data suggest that the presence of intrinsic sympathomimetic activity and cardioselectivity may both be important protective properties which will reduce the incidence of adverse bronchial effects of beta-adrenoceptor–blocking drugs in a population in which the asthmatic patients have been excluded from treatment. These suggestions require investigation by large-scale clinical trials.

Raynaud's phenomenon: Cold extremities and aggravation of the symptoms of Raynaud's phenomenon and peripheral vascular disease are the most frequently reported adverse reactions associated with the use of beta-adrenoceptor–blocking drugs.[24] Aggravation of peripheral vascular disease is often insidious. The patient may present with incipient gangrene of the toes months after the commencement of therapy.[25] In some cases, a history of peripheral vascular disease may not be elicited because the patient cannot walk far enough to develop claudication. The mechanism of this adverse effect is not clearly understood, but the decrease in cardiac output and the increase in peripheral resistance that frequently occur with this group of drugs probably contributes. Drugs with intrinsic sympathomimetic activity have lesser effects on resting cardiac output and have been reported to produce a lower incidence of cold extremities and Raynaud's phenomenon.[5] However, the data are not unequivocal, and Raynaud's phenomenon is seen with all beta-adrenoceptor antagonists. The drugs as a group are contraindicated in peripheral vascular disease.

Cardiac adverse effects: All beta-adrenoceptor–blocking drugs block the heart at least a little and reduce exercise-induced tachycardia. Drugs such as propranolol and timolol, which lack intrinsic sympathomimetic activity, do this to a larger extent than drugs like pindolol and oxprenolol, which possess intrinsic sympathomimetic activity.[4] In a comparative study in hypertensive patients, metoprolol and atenolol (2 cardioselective drugs that lack intrinsic sympathomimetic activity) were shown to have a 30% incidence of significant bradycardia, defined as the development of pulse rates of <55 beats/min; some patients had heart rates <50 beats/min.[10] The negative inotropic properties of beta-blocking drugs are also known to contribute to the cardiac failure that can develop, particularly in elderly patients, during treatment with beta-adrenoceptor–blocking drugs. Whether drugs with intrinsic sympathomimetic activity, which have fewer negative inotropic effects, are less likely to induce cardiac failure is not certain.

Also of concern are reports of rebound arrhythmias that occur upon withdrawal of treatment with beta-adrenoceptor–blocking drugs. Miller et al[6] reported a series of 20 patients with angina treated with propranolol who subsequently stopped treatment. Six of these patients had serious myocardial events: 1 died suddenly, 1 had a myocardial infarction, another developed ventricular tachycardia, and 3 developed coronary insufficiency.

Many adverse cardiac events have been reported after cessation of therapy with beta-adrenoceptor–blocking drugs, but almost all have involved drugs with little or no intrinsic sympathomimetic activity. Ross et al[7] have reported that these drugs produced hypersensitivity of beta-adrenoceptors and cessation of treatment results in rebound tachycardia during exercise. Prichard et al (personal communication) demonstrated a similar rebound tachycardia with propranolol and atenolol, but not with pindolol. These data suggest that a certain level of intrinsic sympathomimetic activity may protect against the development of withdrawal effects.

Metabolic effects: Release of insulin from the beta cells of the pancreas is increased by beta-adrenoceptor

agonists and reduced by alpha-adrenoceptor agonists.[26] The beta adrenoceptors involved have been identified as mainly of the $beta_2$ type.[27] However, these adrenoceptors probably play only a relatively minor role in regulating glucose homeostasis. Evidence for this includes the minimal effect of an intravenous infusion of an alpha- or a beta-adrenoceptor–blocking drug on resting insulin levels[28] and the small effect of beta-adrenoceptor–blocking drugs on glucose tolerance.[29] Alpha and beta adrenoceptors also have little direct effect on the release of pancreatic glucagon.[30]

In other areas of glucose homeostasis, the sympathetic nervous system appears to play a greater role. During hypoglycemia for example, adrenaline and noradrenaline stimulate hepatic glycogenolysis and gluconeogenesis, leading to a normalization of the blood sugar level.[31] Although this effect is believed to be mediated mainly through hepatic alpha adrenoceptors,[32] several studies have shown that beta-adrenoceptor–blocking drugs can delay the recovery of the blood sugar level in normal volunteers after challenge with insulin.[33–35] Beta adrenoceptors may play some role in the process, or else propranolol hinders hepatic glucose production indirectly, perhaps by reducing the blood lactate response to hypoglycemia or by blocking glycerol release.[35,36] In studies in normal volunteers, the recovery of the blood sugar level has been more rapid in subjects given $beta_1$-selective agents,[33,37] and this is one reason why their use has been advocated in diabetic patients liable to hypoglycemia.

However, the generalization of results from normal volunteers to diabetic patients might not be warranted. In a recent study comparing the effects of oxprenolol, metoprolol and placebo on the hypoglycemic response to insulin, the rate of plasma glucose recovery after hypoglycemia was found to be grossly impaired in diabetic patients and unaffected by treatment with beta-blocking drugs.[38] Hypoglycemic symptoms were also similar in the placebo and drug-treated groups, although sweating was more frequent in those taking the beta-adrenoceptor–blocking agents.

Nevertheless, the choice between $beta_1$-selective and nonselective drugs in diabetic patients prone to hypoglycemia may still be important by virtue of their differing effects on the cardiovascular responses to hypoglycemia. With propranolol and other nonselective compounds, both systolic and diastolic pressure may increase sharply, presumably as a consequence of unopposed alpha-adrenoceptor stimulation[37] in association with excessive sympathetic activity. In studies with $beta_1$-selective agents, this effect is less pronounced.[37,38]

Beta Blockers in Ischemic Heart Disease

CLAES WILHELMSSON, MD and ANDERS VEDIN, MD

Many trials have reported that beta blockers increase survival after myocardial infarction; these trials are reviewed. The timolol trial was randomized and showed that mortality was reduced for all patients randomized to beta blockers. Similar findings have been found in both the metoprolol trial in Göteburg and the Beta-Blocker Heart Attack Trial in the U.S. Chronic beta-blockade therapy appears to reduce mortality in patients who survive acute myocardial infarction. The mechanism is as yet unknown.

Myocardial infarction (MI) is a major cause of death in the Western world. Approximately 50% of all deaths in men aged 50 to 64 years are caused by cardiovascular diseases. Most deaths occur outside the hospital. The high incidence of MI has initiated different intervention studies. The first clinically useful beta blocker, propranolol, became available in 1964. Shortly thereafter, Snow[1] published an open study with propranolol in 93 patients after acute MI, showing a significant mortality reduction. Many trials since then have evaluated the effect of beta-blockade on survival both during the acute MI and during the long-term follow-up. The methods of the trials have been refined during the last decade. Many well-controlled trials have shown that beta blockade may reduce long-term mortality in MI patients. In the last year, total mortality has been reduced after acute administration of beta blockers. This report reviews the role of beta blockers in ischemic heart disease.

Prospective Randomized Trials

Since the late 1960s, retrospective and prospective trials have reported an increased survival among patients with MI. Several trials are inconclusive, and most did not contain a representative group of patients[2–5] (Table I). One with too few patients had too few end points to produce meaningful results.[2] In the study by Barber et al,[6] a high oral dose of practolol was administered as soon as possible after the onset of symptoms. There was no significant difference between placebo and practolol treatment. However, in 1 retrospective analysis, patients with fast heart rates on entry seemed to have an improved survival. If sudden death is used as a major end point, the late mortality rate is somewhat lower in the practolol group.

The first positive trial was published from our center in 1974, and several large and well-conducted studies have documented the positive effect of long-term beta blockade in patients with MI since (Table II). In the Gothenburg alprenolol study, 230 patients from 57 to 67 years of age were separated into 4 different risk groups.[7,8] In each separate group, the patients were randomly allocated to treatment with either 400 mg/day of alprenolol or placebo. After inclusion, only 8 patients were withdrawn from the placebo and 8 from the alprenolol groups. None of these patients died or had a reinfarction before the completion of the follow-up. The prospective stratification was successful in that there were no deaths in the low-risk group receiving either placebo or alprenolol. Thus, the reduction of the number of sudden deaths was statistically significant when this difference was analyzed for relevant combinations of groups (Fig. 1). Total mortality was reduced by 50%. The number of nonfatal reinfarctions did not differ between the alprenolol and placebo groups. This study has been criticized for 3 major reasons: the small number of patients in the study and, therefore, a too low level of statistical power; a high frequency of digitalis treatment; and the lack of statistical significance for the

TABLE I Inconclusive Prospective Postinfarction Trials

effect on total mortality. Although small, the group of patients under study was representative of all the infarction cases in Göteborg. It has been suggested that alprenolol may act only by reducing fatal digitalis-induced ventricular arrhythmias, but information about digitalis is not available from other trials. Digitalis and alprenolol may have a synergistic effect, thus decreasing fatal ventricular arrhythmias. The prevalence of digitalis treatment is unlikely to have any significant effect, since the long-term mortality rate in Sweden is the same as that in other European countries. Also, the prevalence of digitalis treatment was the same among survivors and among those who died in both alprenolol and placebo groups.

In many countries, specific or mode-specific mortality as end points are difficult to use due to the uncertain causes of death when the autopsy rate is low. In Gothenburg, the autopsy rate was high (90%). Alprenolol was unlikely to affect noncardiac deaths. There fore, the difference for total mortality is less than tha for sudden cardiac mortality, and the reduced sudde death rate implies a meaningful reduction of tota mortality.

The Multicentre International Practolol Trial[9,1] clearly demonstrates a difference regarding both sudde and cardiac mortality among patients in the stud (Table III). The low placebo mortality rate reflects tha the patients were not representative of all postinfarctio cases. Pretrial exclusions were not detailed and thes findings cannot be used to generalize. No prognosti stratification was used. A retrospective analysis wa carried out in order to define target patients with maximal benefit from treatment with practolol. Th analysis indicated that low body weight, low prerar domization diastolic pressures and site of infarctio were important variables in selecting patients. Ther was an excessive number of early deaths in the practo lol-treated patients who had inferior infarctions. Bod weight was inversely correlated with practolol plasm levels, suggesting a dose-response relationship. A defec of such a retrospective analysis is that it may not be basis for therapeutic recommendation, but help to in tiate new trials that have to use prognostic stratificatio For all randomized patients, practolol did not signif cantly reduce the total mortality, which is probably du to the high mortality among the patients withdraw from the study.

The aim of the Copenhagen trial[11] was to study shor and long-term mortality as well as tolerance for alprer

olol in elderly patients. Treatment was begun on admission to the coronary care unit, when patients were allocated randomly to treatment with intravenous alprenolol or placebo. Oral maintenance treatment ensued and the patients were followed for 1 year after admission. Prognostic stratification was made on the basis of age, heart rate and degree of impaired consciousness at admission. Pretrial exclusions have been detailed. In patients <65 years, treatment and placebo groups were comparable. In patients >65 years, the placebo group was biased toward a worse prognosis than the alprenolol group. For all randomized patients, total mortality was reduced among those <65 years (Fig. 2). In patients with a diagnosis of definite myocardial infarction, mortality was reduced for the short-term (28 days) period; this was not true for all randomized patients. Ventricular arrhythmias and creatine phosphokinase release were reduced among the alprenolol patients, particularly if treatment was instituted soon after onset of symptoms. The findings were different in patients >65 years. Patient intake in this age group was stopped for ethical reasons. There was no difference between alprenolol and placebo regarding the total mortality. The outcome in the placebo group may be partly expected, based on the high number of previous infarctions. In patients with first infarctions, mortality was not reduced. Overall, the excess mortality was explained by a combination of a history of MI and signs of unstable circulation on admission but before randomization.

The Norwegian timolol trial,[12] designed by our group, showed that total mortality was reduced for all randomized patients and also for all presented subsets of patients. The design was stratified and the numbers were large. The patients were representative of a general population, and all pretrial exclusions have been clearly presented. Mortality data for patients excluded before randomization will become available. The groups were

reasonably balanced and analyses ascertained that the small differences found on entry did not influence the results. Timolol reduced mortality by 39% (Fig. 3), sudden death by 45%, and nonfatal reinfarction by 28%. Enough patients were included to make an analysis of adverse effects meaningful. Adverse effects were more common in the timolol group, but they may be considered minor in view of the reduction of mortality. The clinical need to treat patients with a beta blocker was the major reason for withdrawal from the study.

The effect of metoprolol on the 3-month mortality rate was examined in a double-blind stratified randomized trial in patients with definite or suspected acute MI in Göteborg, Sweden.[13] Treatment with metoprolol or placebo was started as soon as possible after the patient's arrival in the hospital and was continued for 3 months. Metoprolol was given as a 15-mg intravenous dose followed by oral administration of 100 mg twice daily. The trial included 1,395 patients who were allocated to various risk groups; within each group, patients were randomly assigned to treatment with metoprolol or placebo. Sixty-two patients in the placebo group (8.9%) and 40 in the metoprolol group (5.7%) died ($p < 0.03$). Mortality was reduced by 36% (Fig. 4). This study was the first to show a beneficial effect on short-term mortality rate after early initiation of treatment.

The Beta-Blocker Heart Attack Trial (BHAT),[14] sponsored by the National Heart, Lung, and Blood Institute, was a randomized, double-blind, multicenter trial of propranolol versus placebo in 3,837 patients. The study showed a 26% reduction of total mortality (Fig. 5). The design comprised a dose titration from 120 to 240 mg/day. The cumulative placebo mortality is low after 30 months of follow-up. The study was closed prematurely on advice from the Policy and Data Mon itoring Board.

The corroborative evidence of propranolol after M is also shown in another trial.[15] This study was pro spective, randomized and double-blind in a high-ris group of MI patients. Altogether, 560 patients entere the trial and were treated with 40 mg of propranolol times daily or with placebo. After 1 year, sudden death were reduced in the propranolol-treated group (Fig. 6) but total mortality or nonfatal reinfarctions were not

Conclusions

Several positive prospective studies strongly suppor the concept that chronic beta blockade of patient during the postinfarction period effectively reduce mortality. The question remains whether the short-terr mortality during the hospital period can be also be re duced. Only 2 early-entry studies have shown a decreas of long-term mortality.[11,13]

The findings in the studies with alprenolol, practolo timolol, metoprolol, and propranolol are probably no due to chance. How different beta blockers reduc mortality is not known, and one must be cautious i ascribing this secondary preventive effect to all bet blockers. In the next 6 months, several secondary pre ventive trials using other beta blockers may answer thi question. The available beta blockers vary in $beta_1$ an $beta_2$ affinity, intrinsic sympathomimetic activity an membrane stabilization activity. There is evidence t suggest that 1 ancillary property of beta blockers i clinically more useful than another. The only charac teristic common to all beta blockers with a positive ef fect on survival is $beta_1$-receptor blockade.

It is difficult to refrain from giving postinfarctio patients alprenolol, timolol, metoprolol or propranolc as long-term standard treatment. In Göteborg, long term administration of beta blockers has been use routinely after MI since 1975. Ideally, treatment shoul be reserved only for patients likely to derive benefi

from the treatment. Since some 60% of postinfarction patients have traditional indications for beta blockers, such as hypertension or angina pectoris, the problem of selecting patients for secondary prophylaxis is diminished. Mortality can be better predicted than reinfarction, but several studies have also shown a decreased reinfarction rate (Table II), suggesting that all patients should be treated.

The Effect of High-Dose Intravenous Nitroglycerin on Cardiovascular Hemodynamic Features and Left Ventricular Function at Rest and During Exercise in Patients With Exertional Angina

PHILLIP J. HARRIS, MB, DPhil, FRACP, GARY S. ROUBIN, MB, FRACP, NORMAN N. SADICK, MB, FRACP, CHRISTOPHER Y.-P. CHOONG, MB, GEORGE BAUTOVICH, MB, FRACP, and DAVID T. KELLY, MB, FRACP

Intravascular pressures, cardiac output and left ventricular function were measured at rest and during exercise in 14 patients with stable angina pectoris before and during an intravenous nitroglycerin infusion. Nitroglycerin was infused at a rate sufficient to reduce mean arterial pressure at rest by 15 to 25 mm Hg.

At rest, the end-diastolic volume index decreased from 57 ± 13 to 39 ± 3 ml/m^2, stroke volume index from 32 ± 6 to 24 ± 5 ml/m^2 and mean arterial pressure from 112 ± 16 to 91 ± 14 mm Hg. The cardiac output was maintained by an increase in heart rate from 73 ± 9 to 92 ± 37 beats/min. The left ventricular ejection fraction increased from 57 ± 7 to 62 ± 9% because the stroke volume decreased less than the end-diastolic volume.

All 14 patients were limited by angina in the prenitroglycerin exercise study, and the mean ST-segment depression at maximal work load was 2.2 ± 1.2 mm. At identical work loads in the nitroglycerin study, only 4 patients had angina, and the mean ST-segment depression was 0.3 ± 0.5 mm. Ten of the 14 patients improved their exercise performance by at least 30 W.

Comparing the 2 exercise studies at the maximal work load achieved in the prenitroglycerin study, the mean pulmonary artery wedge pressure was decreased from 23 ± 6 to 6 ± 4 mm Hg, the end-diastolic volume index from 38 ± 15 to 27 ± 12 ml/m^2 and the mean arterial pressure from 132 ± 8 to 114 ± 13 mm Hg. The stroke volume index and the heart rate were not significantly altered and the ejection fraction increased from 56 ± 8% to 66 ± 8%.

Thus, in the high dose administered, nitroglycerin decreased left ventricular filling pressure, heart size and stroke volume at rest and increased the ejection fraction. During exercise, nitroglycerin decreased myocardial ischemia and improved exercise tolerance. An increase in exercise ejection fraction was associated with an increase in the ratio of systolic pressure to end-systolic volume, suggesting that there was an improvement in contractile performance.

With the resurgence of interest in antianginal drugs, nitroglycerin has become the standard with which new drugs are compared. However, the hemodynamic effects of nitroglycerin are complex and still not completely understood,[1] although it is generally accepted that they are important in reducing myocardial ischemia.[2]

Early studies demonstrated that nitroglycerin is a potent dilator of capacitance vessels,[3] causing a marked reduction in ventricular preload.[4,5] Recent studies using radionuclide ventriculography have described the effect of nitroglycerin on cardiac volume at rest and during exercise. Sorensen et al[6] reported that in normal subjects during exercise, nitroglycerin decreases end diastolic volume with no change in ejection fraction. Slutsky et al[7] and Borer et al[8] demonstrated that in patients with coronary artery disease, nitroglycerin increases the ejection fraction during exercise.

In this study, hemodynamics and left ventricular (LV) function were measured simultaneously at rest and during exercise, before and after intravenous nitro

glycerin, in patients with ischemic heart disease to further delineate its effects on cardiac work load and performance.

Methods

Patients: Fourteen men with a typical history of stable effort angina of >3 months' duration and a positive exercise test result associated with angina were studied. Three patients had had a previous myocardial infarction and 11 had significant coronary disease demonstrated by coronary angiography. All medications were stopped for 1 week before the study, except short-acting nitrates, which were omitted for 12 hours.

On the morning of the study, a radial artery cannula and a No. 7Fr Swan-Ganz thermodilution catheter were inserted percutaneously. Simultaneous hemodynamic and radionuclide measurements were made at rest and during exercise with the patient positioned semisupine 45° to the horizontal on an exercise table attached to an electronically braked bicycle ergometer. The zero reference point for pressures was set at the fourth intercostal space in the midaxillary line.

The exercise work load was increased by 15 W every 3 minutes. Patients were asked to exercise until prevented by symptoms from continuing. When angina was the limiting symptom, they were asked to continue exercising until they had angina of at least moderate severity compared with their usual exertional episodes.

During exercise, heart rate, electrocardiographic lead CM5, radial artery pressure and pulmonary artery pressure were recorded continuously. A 12-lead electrocardiogram was recorded every minute. Cardiac output was measured by thermodilution using an Instrumentation Laboratory computer (model 701) and ice-cold 5% dextrose solution. Five cardiac output measurements were made at rest. During exercise, at least 3 cardiac output measurements were made in the last 1.5 minutes of each 3-minute exercise level.

Simultaneous radial and pulmonary artery blood samples were collected at rest and at the end of each exercise level for measurement of oxygen saturation. The radial artery sample was also used for measuring hemoglobin at rest and during exercise. The arteriovenous oxygen content difference was calculated as 1.39 × the difference between radial artery and pulmonary artery oxygen saturations × hemoglobin level. Oxygen consumption was calculated as the cardiac output × arteriovenous oxygen difference.

Radionuclide ventriculography: Multiple-gated equilibrium radionuclide ventriculography was performed after in vivo labeling of red cells with technetium-99m.[9] Imaging was performed in a modified left anterior oblique position by an Ohio nuclear gamma camera (Sigma 420) equipped with a 30° slant-hole, high-sensitivity collimator, and interfaced to a PDP-11 computer. Counts were collected for 6 minutes at rest with simultaneous recordings of intravascular pressures and cardiac output. During exercise, counts were collected in the last 2 minutes of each 3-minute stage. The composite cardiac cycle was divided into 24 frames for analysis by a variable region of interest. LV ejection fraction was calculated from the background-corrected time-activity curve.[10] Stroke volume was calculated from the thermodilution cardiac output normalized for body surface area and expressed as the stroke volume index. End-diastolic volume index was calculated by dividing the thermodilution stroke volume index by the radionuclide ejection fraction. End-systolic volume index was calculated as end-diastolic volume index minus the stroke volume index.

A control rest and exercise study was performed 1 hour after insertion of the catheters. Patients were then allowed to recover from the control exercise for 2 hours before an intravenous infusion of nitroglycerin was started. Nitroglycerin was administered as a 500 μg/ml solution using a microdrip burette with polyvinyl tubing and a volumetric infusion pump (IMED 922). This report describes the effect of administering a high

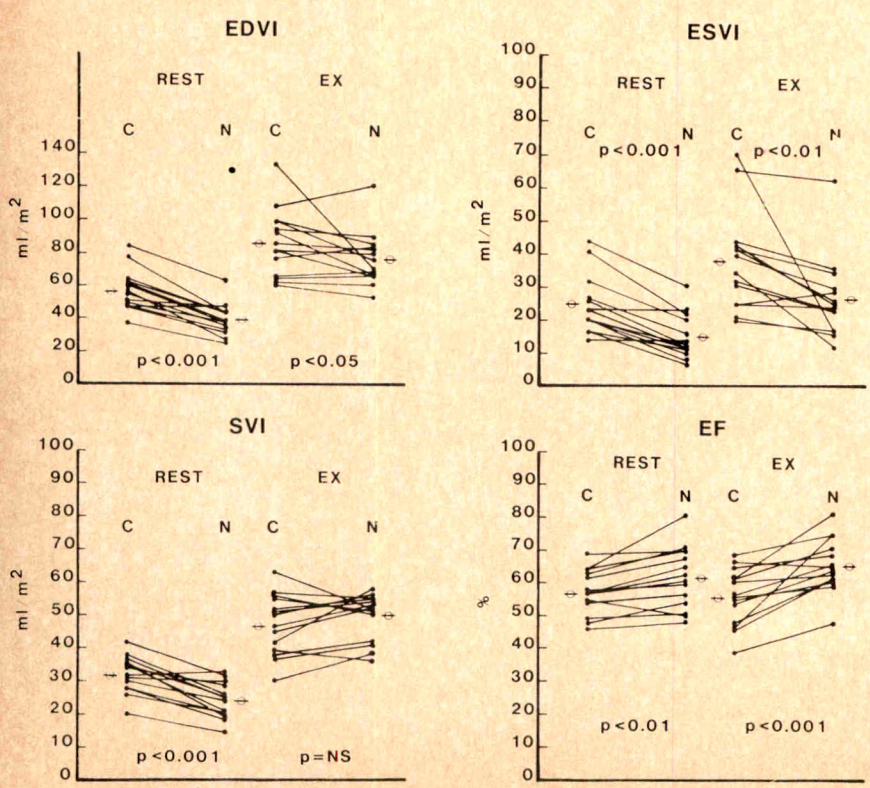

FIGURE 1. End-diastolic volume index (EDVI), end-systolic volume index (ESVI), stroke volume index (SVI) and ejection fraction (EF) in control (C) and nitroglycerin (N) studies at rest and during exercise (EX). The exercise studies were compared at identical work loads for each patient. p = probability; NS = not significant.

dose of nitroglycerin. The infusion rate was started at 0.17 ml (83 μg)/min and increased by 0.17 ml/min every 5 minutes until the mean arterial blood pressure decreased by 15 to 25 mm Hg. When this end point had been reached, the infusion was maintained at a constant rate. After a further 15 minutes of observation to ensure a steady state, repeated rest and exercise observations were performed during the nitroglycerin infusion. The final infusion rates ranged from 0.17 ml (83 μg)/min to 0.75 ml (375 μg)/min (mean 0.42 ml[208 μg]/min). Allowing for the rate of adsorption to plastic tubing measured in our laboratory, the dose actually received by the patient probably ranged from 0.52 to 3.57 μg/kg/min (mean 1.28).

Unless otherwise stated, results are expressed as mean ± standard deviation. Hemodynamic features and LV function at rest and exercise during the nitroglycerin infusion were compared with results during the control rest and exercise study using a 3-way analysis of variance, unless significant interaction was detected, in which case control and nitroglycerin studies were compared at rest and during exercise using a paired *t* test.

Results

Rest: The effect of nitroglycerin on LV volume and function are shown in Figure 1. At rest, the end-diastolic volume index decreased from 57 ± 13 to 39 ± 13 ml/m^2 and end-systolic volume index decreased from 24 ± 17 to 15 ± 7 ml/m^2. Because end-diastolic volume decreased to a greater extent than end-systolic volume, the stroke index decreased from 32 ± 6 to 24 ± 5 ml/m^2. The resting LV ejection fraction increased from 57 ± 7 to 62 ± 9%.

Mean arterial pressure was reduced by the nitroglycerin infusion from 112 ± 16 to 91 ± 14 mm Hg and systemic vascular resistance was reduced from 2,082 ± 471 to 1,805 ± 372 dynes s cm^{-5} (Fig. 2). Mean pulmonary artery wedge pressure decreased from 3 ± 2 to 1 ± 2 mm Hg.

Heart rate increased from 73 ± 9 to 92 ± 27 beats/min (Fig. 3). This increase in heart rate compensated for the decrease in stroke volume, and there was no significant reduction in cardiac index. The increase in heart rate was also accompanied by an increase in the ratio of the peak systolic pressure to end-systolic volume index (systolic pressure volume ratio) from 7.4 ± 2.8 to 10.1 ± 5.1 (Fig. 3).

Exercise: All patients stopped with angina in the control study. The mean ST-segment depression at the maximal work load was 2.2 ± 1.2 mm. The mean oxygen consumption was 15.9 ± 5.3 ml/kg, compared with 3.5 ± 0.3 ml/kg at rest. At the same work load for each patient during the nitroglycerin infusion, only 4 of the 11 patients had angina, which was milder than in the control study, and the mean ST-segment depression was 0.3 ± 0.5 mm.

End-diastolic and end-systolic volume increased significantly above resting levels during both exercise studies (Fig. 1). When compared at the maximal work load achieved during the control study, the end-diastolic volume index and the end-systolic volume index were lower during the nitroglycerin study than during the control study. The reduction in end-systolic volume index, from 38 ± 15 to 27 ± 12 ml/m^2, was similar to the reduction in end-diastolic volume index, from 86 ± 21 to 76 ± 16 ml/m^2; the stroke index was the same during control (47 ± 9 ml/m^2) and nitroglycerin (49 ± 7 ml/m^2) exercise. However, the ejection fraction was higher

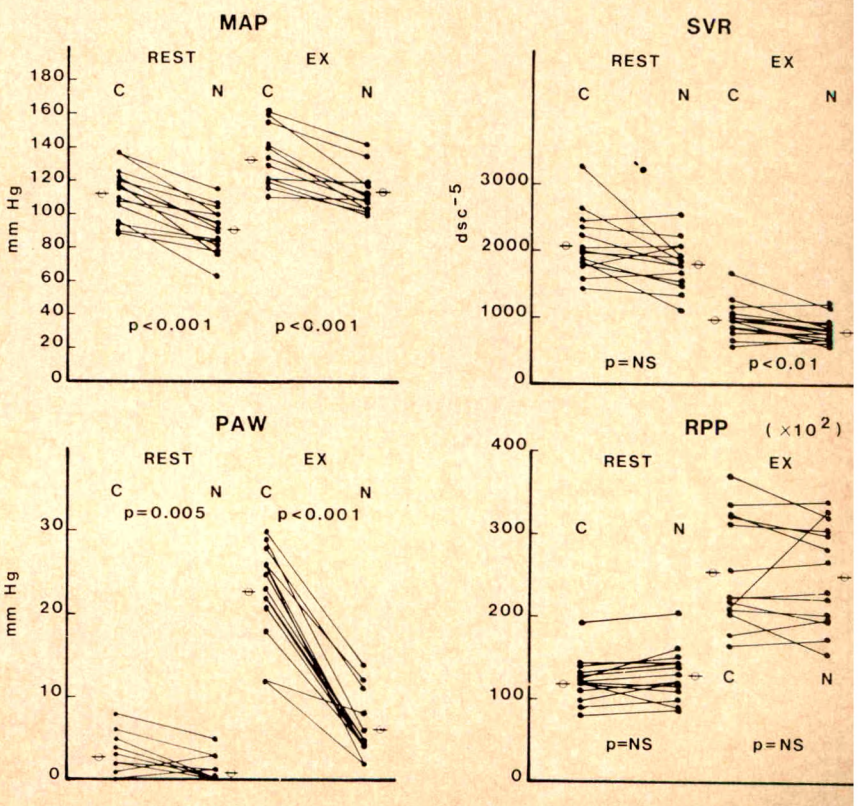

FIGURE 2. Mean arterial pressure (MAP), systemic vascular resistance (SVR), pulmonary artery wedge pressure (PAW) and rate-pressure product (RPP) in control (C) and nitroglycerin (N) studies at rest and during exercise (EX). The exercise studies were compared at identical work loads for each patient. p = probability; NS = not significant.

during the nitroglycerin exercise (66 ± 8 versus 56 ± 8%). The mean pulmonary artery wedge pressure increased dramatically during exercise, to 23 ± 6 mm Hg. This increase was attenuated during the nitroglycerin infusion, and at the same work load it was only 6 ± 4 mm Hg (Fig. 2).

The vasodilator effect of nitroglycerin was maintained during exercise and the mean arterial pressure at identical work loads was 132 ± 8 mm Hg in the control study, compared with 114 ± 13 mm Hg in the nitroglycerin study (Fig. 2). Heart rate was slightly higher during the nitroglycerin study compared with control, but the difference was not significant (Fig. 3). The rate-pressure product (heart rate × systolic arterial pressure × 10^{-2}) did not differ significantly: At identical work loads it was 254 ± 66 in the control study and 251 ± 30 in the nitroglycerin study (Fig. 2). Although systemic vascular resistance decreased from rest during both exercise studies, it remained lower during the nitroglycerin study (Fig. 2).

At identical work loads, there was no significant difference in arteriovenous oxygen difference (Fig. 3). However, the cardiac index was slightly higher in the nitroglycerin study (6.0 ± 1.2 versus 5.5 ± 1.2); the systolic pressure-volume ratio was significantly higher in the nitroglycerin study (9.1 ± 4.1 versus 6.6 ± 3.3) (Fig. 3).

The reduction in myocardial ischemia produced by nitroglycerin at identical work loads was accompanied by a significant improvement in exercise performance. Thirteen of 14 patients improved their exercise tolerance by at least 1 exercise level (15 W) and 10 patients improved by at least 2 exercise levels (30 W). Oxygen consumption at peak exercise during the nitroglycerin study was 23.4 ± 6.6 ml/kg/min, an average increase of 7.5 ml/kg/min, or approximately 2.4 METS, over the control study. At peak exercise during the nitroglycerin study, there was 1.2 ± 1.2 mm of ST depression. Of the 13 patients who improved their exercise tolerance, 5 did not have angina during the nitroglycerin study and 3 had it only very mildly (compared with the control study), and it was not the limiting factor.

Hemodynamic values at the maximal work load in the control study and at the maximal work load in the nitroglycerin study are shown in Table I. In achieving the increased exercise performance, the end-diastolic volume index, pulmonary artery wedge pressure and mean arterial pressure remained below the levels reached during control exercise. In contrast, heart rate, cardiac index, arteriovenous oxygen difference and rate-pressure product increased to levels significantly higher than those achieved during the control exercise period. Although the ejection fraction remained significantly higher at peak exercise, during nitroglycerin the systolic pressure-volume ratio was not significantly different.

Discussion

The hemodynamic response to nitroglycerin is influenced by the broad range of individual sensitivities to the drug and by the variable effect that different dose levels have on venous, arterial and arteriolar smooth muscle.[1,2] In the present study, these factors were controlled by giving nitroglycerin intravenously at a rate

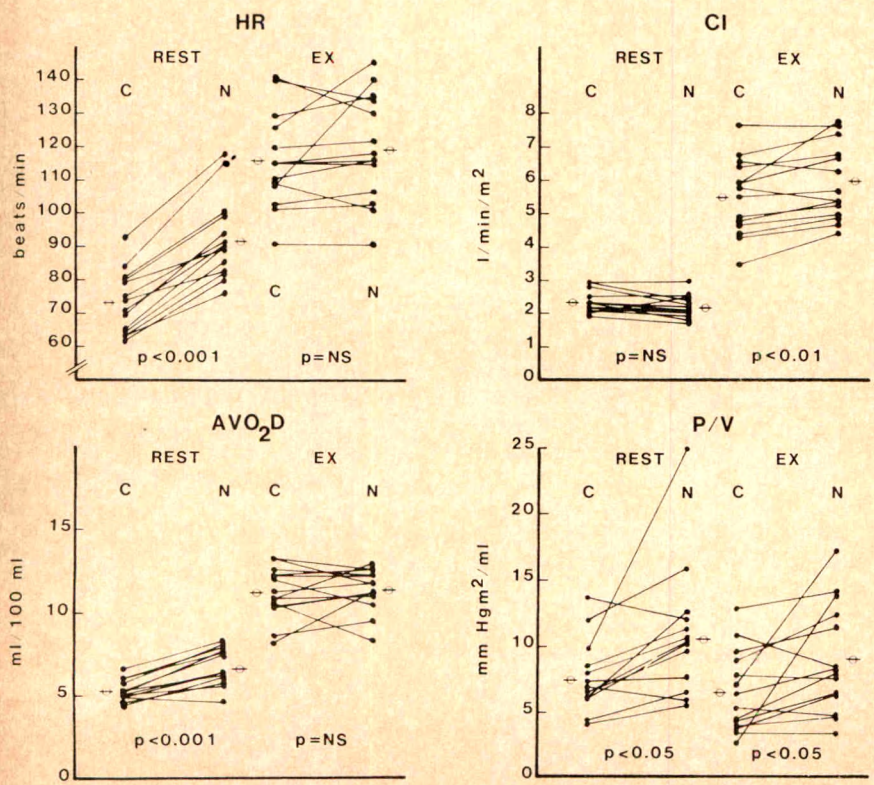

FIGURE 3. Heart rate (HR), cardiac index (CI), arteriovenous oxygen content difference (AVO_2D) and ratio of peak systolic pressure to left ventricular end-systolic volume index (P/V) in control (C) and nitroglycerin (N) studies at rest and during exercise (EX). The exercise studies were compared at identical work loads for each patient. p = probability; NS = not significant.

TABLE I Hemodynamic Values and Left Ventricular Function at Maximal Work Load in Control and Nitroglycerin Exercise Studies

	Control	Nitroglycerin	p
EDVI (ml/m^2)	86 ± 20	79 ± 28	<0.05
ESVI (ml/m^2)	38 ± 15	36 ± 4	NS
SVI (ml/m^2)	47 ± 9	52 ± 8	<0.05
EF (%)	56 ± 8	63 ± 8	<0.01
P/V ratio	6.6 ± 3.1	7.6 ± 3	NS
PAWP (mm Hg)	23 ± 6	9 ± 4	<0.001

CI (liters/min/m^2)	5.5 ± 1.2	7.1 ± 1.3	<0.001
AVO_2D	11.2 ± 1.6	13 ± 1.3	<0.05

AVO_2D = arteriovenous oxygen content difference; CI = cardiac index; EDVI = end-diastolic volume index; EF = ejection fraction; ESVI = end-systolic volume index; HR = heart rate; MAP = mean arterial pressure; PAWP = pulmonary artery wedge pressure; P/V ratio = peak systolic pressure to end-systolic left ventricular volume ratio; RPP = heart rate × systolic arterial pressure; SVI = stroke volume index; SVR = systolic vascular resistance.

sufficient to produce a similar reduction in LV filling pressure and arterial pressure in all patients.

Nitroglycerin usually causes a decrease in stroke volume at rest secondary to the venodilation and reduction in LV filling pressures.[6,11,12] Occasionally, there may be a profound decrease in cardiac output with bradycardia.[13] In the present study, the decrease in stroke volume was compensated by a reflex increase in heart rate, and cardiac output was maintained. However, there was a decrease in blood pressure and a decrease in systemic vascular resistance, indicating that at the dose rates administered, nitroglycerin dilated arterioles as well as veins.

This study reconciles the reduction in stroke volume at rest caused by nitroglycerin with the reported increase in ejection fraction reported in radionuclide[7,8] and echocardiography[5] studies. Stroke volume decreased less than the end-diastolic volume and the ratio of the 2, the ejection fraction, increased.

This study was designed so that all patients would have angina and ST-segment depression during the control exercise study. The mean work level achieved during the control study was only 5 METS. Although this was an open study, there is reasonable evidence that intravenous nitroglycerin significantly reduced myocardial ischemia during exercise. At identical exercise levels, there was a marked reduction in ST-segment depression; whereas all patients were limited by moderate to severe angina during the control study, at the same work level in the nitroglycerin study, only 4 patients had angina, and it was very mild. The best evidence that nitroglycerin decreased myocardial ischemia was the improvement in exercise performance by an average of 3 METS during the nitroglycerin study. All 13 patients who improved their exercise performance achieved higher heart rates, rate-pressure products, cardiac outputs and ejection fractions compared with the control study.

The large increase in end-diastolic volume during the control exercise study is the usual finding in our laboratory, when patients with stable exertional angina exercise in a semisupine position.[14] This study has demonstrated that the increase in end-diastolic volume was associated with a similar increase in LV filling pressure to levels that would cause significant dyspnea in normal subjects.

It is likely that the LV filling pressures were actually higher than the recorded levels. At rest, the right atrial, pulmonary artery and pulmonary artery wedge pressures were lower than expected. We realized early in the study that the transducers were probably being set several centimeters too high for patients in a semisupine position, thus decreasing the recorded right-sided pressures. However, in the interest of consistency, we set the transducers at the same high level throughout the study.

End-systolic volume decreases when normal persons exercise.[6,7] The increase in end-systolic volume in this and other studies[7,15] when patients with coronary artery disease exercise is 1 of the major manifestations of LV ischemia and it is the mechanism underlying the increase in end-diastolic volume and filling pressures and the flat or decreasing ejection fraction response.

Nitroglycerin markedly reduced the LV filling pressure during exercise and maintained the systemic vascular resistance lower than during the control study. Despite the large decrease in filling pressures during exercise, the effect of nitroglycerin on cardiac volumes during exercise was less than that at rest. Although the reduction in volume was small, it is likely that wall tension, a major determinant of oxygen requirement, was significantly reduced by the lower filling pressure (Fig. 4).

Although nitroglycerin decreased stroke volume at rest, there was no consistent change during exercise and

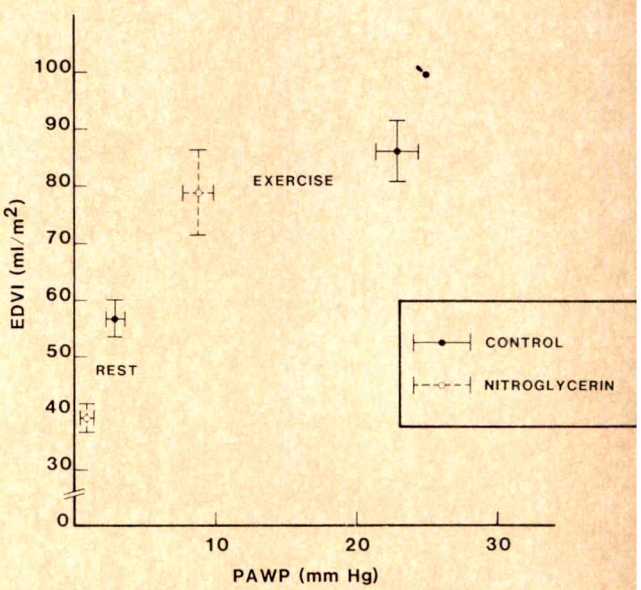

FIGURE 4. Relationship between end-diastolic volume index (EDVI) and pulmonary artery wedge pressure (PAWP) at rest and during exercise at identical work loads. Group mean and standard errors are shown for control studies and after nitroglycerin.

cardiac output tended to be higher during the nitroglycerin study. Thus, unlike beta blockers, which impede cardiac output, nitroglycerin enhances the delivery of oxygen to the exercising muscles. Presumably, the improvement in cardiac output during exercise was related to the absence of ischemic depression of cardiac output.

This study cannot answer the question of whether nitroglycerin improves pump function by a primary increase in myocardial oxygen supply. However, it does provide some evidence as to whether the improved cardiac performance is due to decreased external load alone, with persistent impairment of LV function, or whether there is a real improvement in contractile performance.

The LV ejection fraction is an index of contractile performance, and it was increased during the nitroglycerin study. However, the LV ejection fraction is sensitive to changes in afterload, and there is no doubt that the reduced LV volume and the reduced arterial pressure contributed to a significant reduction in afterload.

The ratio between the peak systolic pressure and the end-systolic volume has recently been explored as an index of the contractile state which takes into account the afterload.[15–17] In this study, nitroglycerin increased the pressure-volume ratio at rest and during exercise. The increase at rest may be due to an increase in contractility secondary to reflex changes stimulated by the reduction in blood pressure.

In both control and nitroglycerin studies, the pressure-volume ratio was lower during exercise than at rest, indicating that at this work level the contractile state of the heart was impaired by ischemia, compared with resting state. Despite this decrease from resting levels, the pressure-volume ratio during nitroglycerin exercise was higher than that during the control study, indicating that the reduction in myocardial ischemia during nitroglycerin exercise was associated with improved contractile performance. As patients exercised to peak work load during the nitroglycerin infusion, the ratio decreased to a level similar to that at maximal exercise in the control study.

In summary, intravenous nitroglycerin was given at a dose which produced both venous and arterial dilatation. At rest, the reduction in preload caused a decrease in stroke volume, but the cardiac output was maintained by an increase in heart rate. During exercise, nitroglycerin produced a significant decrease in myocardial ischemia. Its major effect on hemodynamics was to attenuate the large increase in filling pressure. In contrast to the findings at rest, the reduction in preload during exercise caused only a small decrease in cardiac volume and did not decrease stroke volume. LV ejection fraction was increased; this improvement in cardiac function was possibly due to an improvement in the contractile state because of reduced ischemia, rather than the effect of reduced load alone.

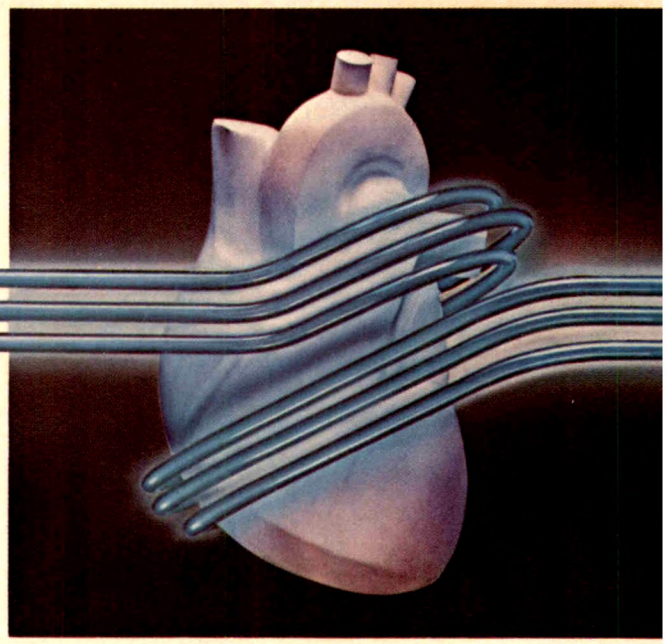
ANGINA PROTECTION AND MORE

—WITH SIMPLE, ONCE-DAILY DOSAGE

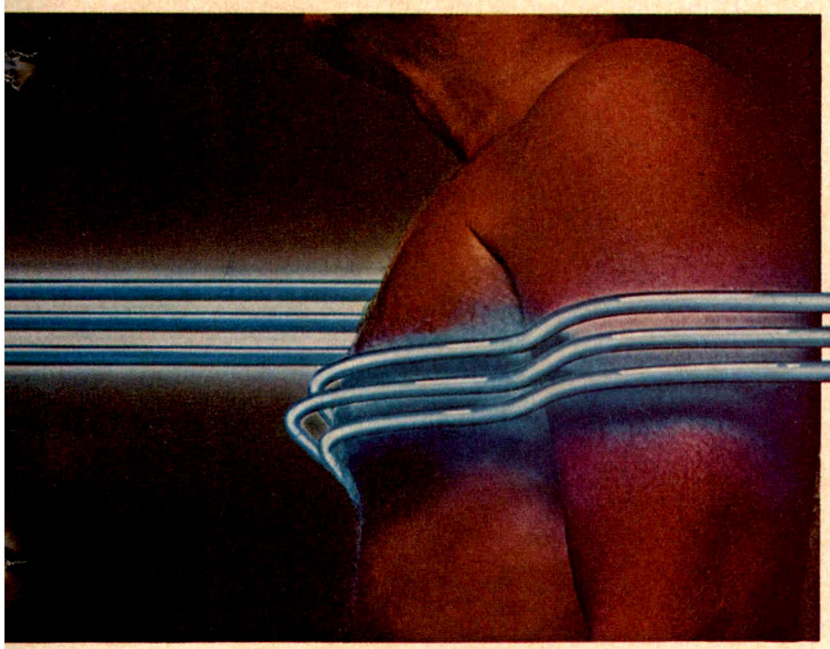


The cardiovascular protection of INDERAL—for simplified core therapy in angina

Once-daily INDERAL LA (propranolol HCl) adds simplicity and convenience to the therapeutic benef of INDERAL in the long-term treatment of angina

INDERAL LA provides smooth, 24-hour beta blockade with single daily dosing–to reduce the fre quency and severity of anginal attacks around the clock. As core therapy, INDERAL LA is compati- ble with other conventional antianginal therapies.

Like INDERAL tablets, INDERAL LA should not be used in the presence of congestive heart failure, sinus bradycardia, heart block greater than first degree, or bronchial asthma.



THE ONE™ TO COUNT ON

Start with 80 mg once daily...

Simplified core therapy begins with 80 mg once daily. Although individual patients may respond to various doses, the average optimal dose in angina pectoris is 160 mg once daily.

When converting patients from other beta blockers, including INDERAL tablets, switch to the nearest milligram equivalent of INDERAL LA once daily and evaluate clinical results to determine if dosage adjustment is necessary. For arrhythmias, use conventional INDERAL (propranolol HCl) tablets.

80 mg 120 mg 160 mg

The appearance of INDERAL LA capsules is a registered trademark of Ayerst Laboratories.

Please see next page for brief summary of prescribing information.

ONCE-DAILY

INDERAL® LA

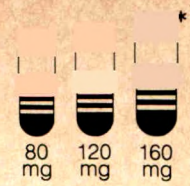
(PROPRANOLOL HCl) LONG ACTING CAPSULES

Ayerst®

UNIVERSITY COLLEGE OF M.A.R.A.
LIBRARY

The one to count on for ANGINA, HYPERTENSION and prevention of MIGRAINE.

ONCE-DAILY INDERAL® LA (PROPRANOLOL HCl) LONG ACTING CAPSULES



BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION SEE PACKAGE CIRCULAR.)*
INDERAL® LA BRAND OF propranolol hydrochloride
(Long Acting Capsules)

DESCRIPTION. Inderal LA is formulated to provide a sustained release of propranolol hydrochloride. Inderal LA is available as 80 mg, 120 mg, and 160 mg capsules.

CLINICAL PHARMACOLOGY. INDERAL is a nonselective beta-adrenergic receptor blocking agent possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available receptor sites. When access to beta-receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

INDERAL LA Capsules (80, 120, and 160 mg) release propranolol HCl at a controlled and predictable rate. Peak blood levels following dosing with INDERAL LA occur at about 6 hours and the apparent plasma half-life is about 10 hours. When measured at steady state over a 24-hour period the areas under the propranolol plasma concentration-time curve (AUCs) for the capsules are approximately 60% to 65% of the AUCs for a comparable divided daily dose of INDERAL tablets. The lower AUCs for the capsules are due to greater hepatic metabolism of propranolol, resulting from the slower rate of absorption of propranolol. Over a twenty-four (24) hour period, blood levels are fairly constant for about twelve (12) hours then decline exponentially.

INDERAL LA should not be considered a simple mg for mg substitute for conventional propranolol and the blood levels achieved do not match (are lower than) those of two to four times daily dosing with the same dose. When changing to INDERAL LA from conventional propranolol, a possible need for retitration upwards should be considered especially to maintain effectiveness at the end of the dosing interval. In most clinical settings, however, such as hypertension or angina where there is little correlation between plasma levels and clinical effect, INDERAL LA has been therapeutically equivalent to the same mg dose of conventional INDERAL as assessed by 24-hour effects on blood pressure and on 24-hour exercise responses of heart rate, systolic pressure and rate pressure product. INDERAL LA can provide effective beta blockade for a 24-hour period.

The mechanism of the antihypertensive effect of INDERAL has not been established. Among the factors that may be involved in contributing to the antihypertensive action are (1) decreased cardiac output, (2) inhibition of renin release by the kidneys, and (3) diminution of tonic sympathetic nerve outflow from vasomotor centers in the brain. Although total peripheral resistance may increase initially, it readjusts to or below the pretreatment level with chronic use. Effects on plasma volume appear to be minor and somewhat variable. INDERAL has been shown to cause a small increase in serum potassium concentration when used in the treatment of hypertensive patients.

In angina pectoris, propranolol generally reduces the oxygen requirement of the heart at any given level of effort by blocking the catecholamine-induced increases in the heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. Propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure and systolic ejection period. The net physiologic effect of beta-adrenergic blockade is usually advantageous and is manifested during exercise by delayed onset of pain and increased work capacity.

In dosages greater than required for beta-blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential. The significance of the membrane action in the treatment of arrhythmias is uncertain.

The mechanism of the antimigraine effect of propranolol has not been established. Beta-adrenergic receptors have been demonstrated in the pial vessels of the brain.

Beta receptor blockade can be useful in conditions in which, because of pathologic or functional changes, sympathetic activity is detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, greater than first degree, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

Propranolol is not significantly dialyzable.

INDICATIONS AND USAGE. Hypertension: INDERAL LA is indicated in the management of hypertension; it may be used alone or used in combination with other antihypertensive agents, particularly a thiazide diuretic. INDERAL LA is not indicated in the management of hypertensive emergencies.

Angina Pectoris Due to Coronary Atherosclerosis: INDERAL LA is indicated for the long-term management of patients with angina pectoris.

Migraine: INDERAL LA is indicated for the prophylaxis of common migraine headache. The efficacy of propranolol in the treatment of a migraine attack that has started has not been established and propranolol is not indicated for such use.

Hypertrophic Subaortic Stenosis: INDERAL LA is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL LA also improves exercise performance. The effectiveness of propranolol hydrochloride in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta-receptor stimulation. Clinical improvement may be temporary.

CONTRAINDICATIONS. INDERAL is contraindicated in 1) cardiogenic shock; 2) sinus bradycardia and greater than first degree block; 3) bronchial asthma; 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS. CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary, they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks, and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL (propranolol HCl), like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS. General: Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose.

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS. Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

DOSAGE AND ADMINISTRATION. INDERAL LA provides propranolol hydrochloride in a sustained-release capsule for administration once daily. If patients are switched from INDERAL tablets to INDERAL LA capsules, care should be taken to assure that the desired therapeutic effect is maintained. INDERAL LA should not be considered a simple mg for mg substitute for INDERAL. INDERAL LA has different kinetics and produces lower blood levels. Retitration may be necessary especially to maintain effectiveness at the end of the 24-hour dosing interval.

HYPERTENSION—*Dosage must be individualized.* The usual initial dosage is 80 mg INDERAL LA once daily, whether used alone or added to a diuretic. The dosage may be increased to 120 mg once daily or higher until adequate blood-pressure control is achieved. The usual maintenance dosage is 120 to 160 mg once daily. In some instances a dosage of 640 mg may be required. The time needed for full hypertensive response to a given dosage is variable and may range from a few days to several weeks.

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 80 mg INDERAL LA once daily, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg once daily. In angina pectoris, the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of a few weeks (see WARNINGS).

MIGRAINE—*Dosage must be individualized.* The initial oral dose is 80 mg INDERAL LA once daily. The usual effective dose range is 160-240 mg once daily. The dosage may be increased gradually to achieve optimum migraine prophylaxis. If a satisfactory response is not obtained within four to six weeks after reaching the maximum dose, INDERAL LA therapy should be discontinued. It may be advisable to withdraw the drug gradually over a period of several weeks.

HYPERTROPHIC SUBAORTIC STENOSIS—80-160 mg INDERAL LA once daily.

PEDIATRIC DOSAGE — At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

*The appearance of INDERAL LA capsules is a registered trademark of Ayerst Laboratories.

Update your echo lab with Cardiac Doppler.

Sonacolor® CD

CARDIAC DOPPLER

The Cardiac Doppler system expands conventional echocardiography by providing noninvasive assessment of flow velocities through all four heart valves. It is all you need to confirm stenotic or regurgitant valvular disease.

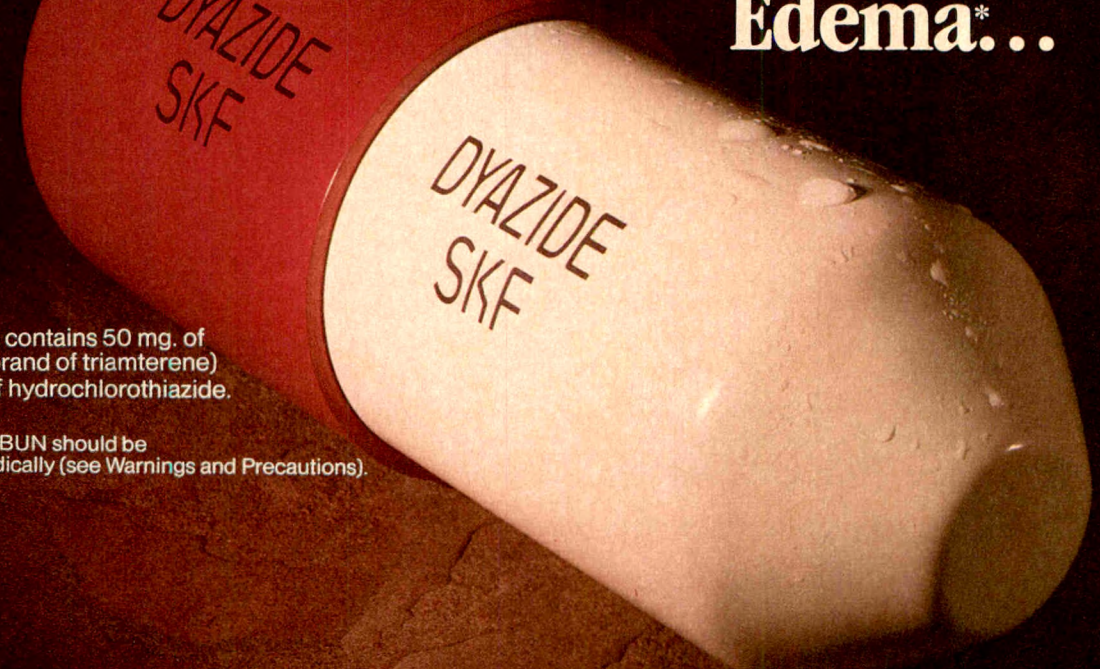
- Color spectral patterns grade the degree of valve stenosis and turbulence.
- Valve cross-sectional areas can be derived from pressure gradient half-times.
- Color spectral patterns grade the degree of regurgitation. Valve prolapse is identified through the presence and timing of regurgitation.
- Detects the high velocity jets of flow through prosthetic valves. Detects prosthetic valve leakage. Monitors valve function over time.
- Color spectral patterns locate and grade shunts.
- Displays ECG trace for time reference. Phono trace for correlation of heart sounds with Doppler flow velocity patterns.
- Computes cardiac output approximation, stroke volume and average flow.

Call 1-800-334-4531 to place your order, for in-depth information or an on-site demonstration.

Carolina Medical Electronics, Inc.

P.O. BOX 307, KING, N.C. 27021 USA, TELEPHONE (919) 983-5132

In Cardiac Edema*...



Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

Serum K^+ and BUN should be checked periodically (see Warnings and Precautions).

When You Need to Conserve K+

Over 17 Years of Confidence

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

* **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, 'Dyazide' should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on 'Dyazide' when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with 'Dyazide'. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with 'Dyazide', but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and 'Dyazide' should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. 'Dyazide' should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances; postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on 'Dyazide', although a causal relationship has not been established.

Supplied: 'Dyazide' is supplied in bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

Once

Now...

Once-a-day antihypertensive efficacy confirmed worldwide

Studies done in the U.S.A., England, Scandinavia and other parts of Europe and Asia have shown that once-a-day dosage of metoprolol significantly reduced both systolic and diastolic pressure.[1-11]

-a-day

cardioselective*

Lopressor®

metoprolol tartrate

New dosage schedule: To start, 100 mg once-a-day, or in divided doses.

Lower doses (especially 100 mg) may not maintain full effect at end of 24-hour period. Measure BP near end of dosing interval, adjust to larger or more frequent dosage if needed.

*exerts a relative preference for beta-one receptors; this preference is not absolute.

Contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure.

Please turn page for brief Prescribing Information.

Geigy

536-5761-A

Now more convenient than ever in once-a-day dosage

Lopressor®
metoprolol tartrate

An antihypertensive beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Prescribing Information

Brief Summary of Prescribing Information.

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative $beta_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since $beta_1$ selectivity is not absolute, a $beta_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. $Beta_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

Mitral Commissurotomy—Still a Good Operation

Recently, I examined an operatively excised, severely stenotic mitral valve that was free of calcific deposits (by radiography of the excised valve) and of associated mitral regurgitation (by left ventricular angiography). The patient had no evidence of dysfunction of either the tricuspid or aortic valves. I asked the surgeon who had performed the mitral valve replacement (MVR) why that procedure was performed rather than mitral valve commissurotomy (MVC). I was surprised to hear that he "rarely did MVC anymore" and that he had "more confidence in MVR than in MVC." He had used a mechanical prosthesis for the MVR, which necessitated anticoagulant therapy for the rest of this 36-year-old woman's life. When I mentioned that chronic anticoagulant therapy would not have been necessary had MVC been performed, he responded that "MVR was still worth the difference." I disagree, and so does Bonchek[1] in the editorial in this issue.

In 1978, Lachman and I[2] radiographed 164 operatively excised stenotic mitral valves and quantitated the amount of calcific deposits in them. Of the 164 valves, 14 had absent and 43 minimal calcific deposits on x-ray examination of the excised valve. Of the 57 patients with absent or minimal calcific deposits, 37 had moderate to severe mitral regurgitation, and therefore, each clearly warranted MVR. The remaining 20 had absent or minimal calcific deposits and absent or minimal mitral regurgitation as determined by left ventricular angiography; nevertheless, MVR had been performed. We analyzed retrospectively those 20 patients to examine if MVR was preferable to MVC.[3]

To answer this question unequivocally, the stenotic mitral valves in patients who had only commissurotomy would have to be studied morphologically and radiographically in the same manner as those that were excised and replaced. Obviously, the nonexcised valve cannot be examined in the same manner as the excised valve. Nevertheless, the ideal valve for MVC in the past has bee considered to be the stenotic one that is free of calcif deposits, free of significant mitral regurgitation, and mobil The excised mitral valves in the 20 patients whom w analyzed were free of calcific deposits by preoperati examination (or nearly so by radiography of the excise valve, a far more sensitive technique than x-ray or flu roscopy through the chest wall), and none had significa regurgitation by left ventricular angiography. The degre of mobility was infrequently described in the operati note. All 20 patients analyzed would probably have bee acceptable candidates for MVC in the pre–valve r placement era. Why, then, might valve replacement b performed with its prosthetic- or bioprosthetic-relat complications rather than MVC in this circumstance?

Of the 20 patients studied by Lachman and me,[3] seve reasons appeared to account for MVR rather than MV (1) *Another cardiac valve was also replaced* (13 patient Therefore, if the patient is required to have anticoagula therapy for a prosthesis in the tricuspid or aortic val position, MVR may be the more reasonable procedure a will avoid the risk of significant regurgitation or incomple relief of the stenosis by MVC. (2) *Cardiopulmonary bypa was used* (all 20 patients). This procedure obviously allo visual inspection of the valve, something not possible wh MVC is done as a "closed" procedure. I suspect that t visually inspected stenotic mitral valve is more frighteni to the observer than is the palpated stenotic valve. Th visual inspection alone, particularly when valve replac ment is a reasonable and uncriticized option, may push t surgeon toward replacement rather than simple co missurotomy in some patients. (3) *Some surgeons h relatively little experience with MVC* (17 patients). Of t 20 patients we analyzed, 17 were operated on by surgec <40 years old when the operation was done. As point out by Bonchek,[1] younger surgeons have had much le

Continued on page A10

experience with MVC than with MVR. (4) *Dissatisfaction with attempted MVC* (3 patients). (5) *Previous MVC had been performed* (11 patients). Although there is disagreement on this point, a mitral valve that has had a commissurotomy and later becomes severely stenotic can nevertheless have another MVC as long as calcific deposits are absent and regurgitation is absent or minimal. (6) *Incorrect identification of mitral calcific deposits* (2 patients). A calcific deposit was described in the mitral leaflets at operation, but x-ray of the excised valve showed that it was devoid of calcium.

Each of these 6 factors contributed in ≥ 1 of the 20 patients analyzed to the final operative decision of MVC rather than MVR. Even though MVC has been performed for >30 years, the mere alternative of MVR appears to have somewhat altered the definition of the mitral valve previously considered ideal for MVC. We need to return to the earlier definition of the ideal mitral valve suitable for MVC.

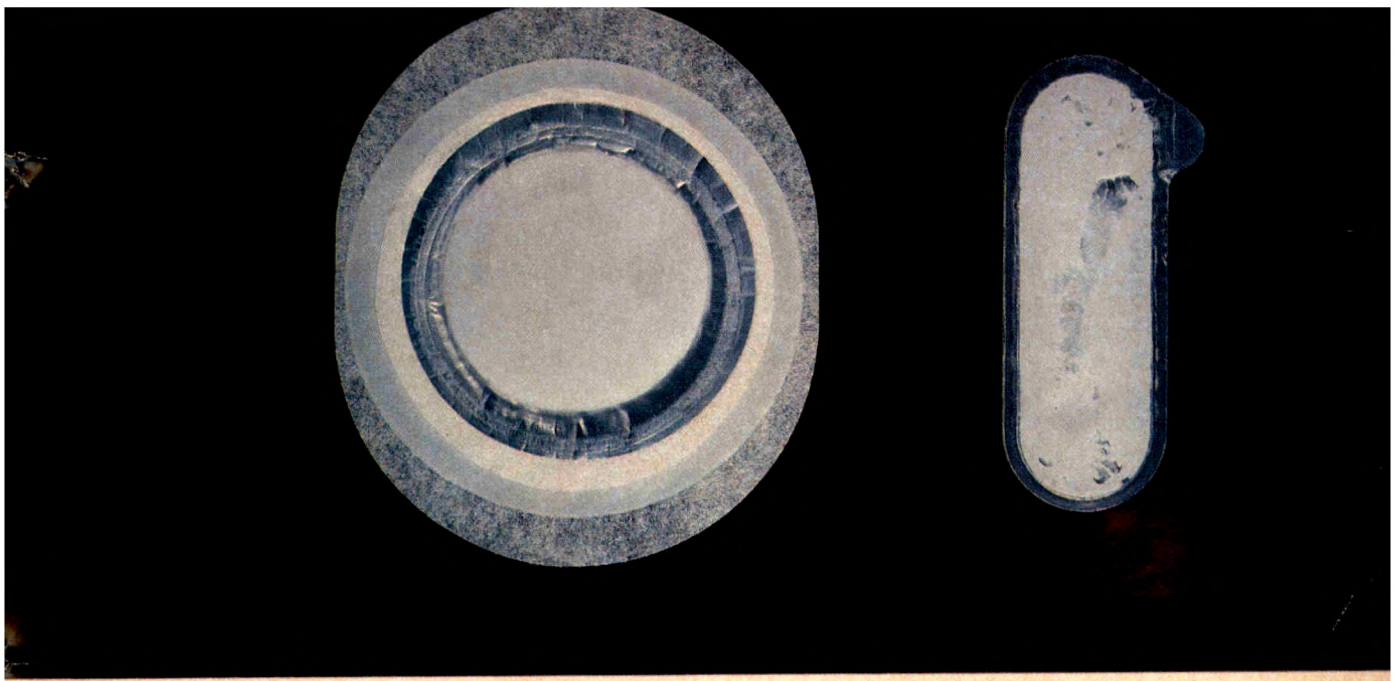
Editor-in-Chief



One costs 13% less.

Nitro-Dur: a significant savings for the angina patient.

When a patient takes a medication every day and possibly for the rest of his life, cost becomes a significant factor.

Nitro-Dur is the most economical transdermal nitroglycerin: the 10 cm^2 size costs 11% less and the 20 cm^2 size costs 13% less than the comparable products from Ciba. In one year, patients using Nitro-Dur can save up to $75 compared to patients using the Ciba product.[1]

Nitro-Dur patients save in another way. The larger adhesive surface of Nitro-Dur means that there is less chance of adhesive failure, thus saving the patient the cost of replacement.

Reduced patient cost. One more reason why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

The most widely prescribed transdermal nitroglycerin system.

Please see next page for a summary of prescribing information.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release in vivo of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[2] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

INDICATIONS AND USAGE: Prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28 and hospital packs of 100.

CAUTION: Federal law prohibits dispensing without a prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

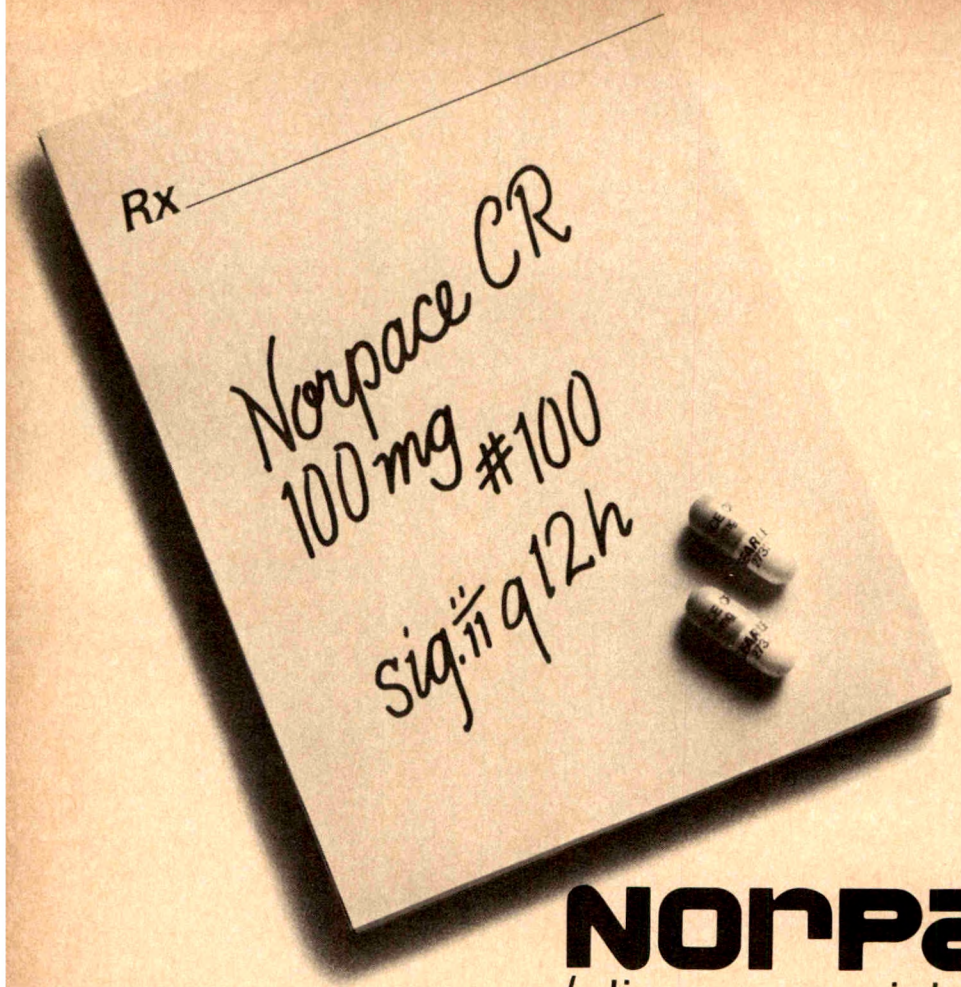
his doctor prescribed...
NORPACE® CR
(disopyramide phosphate)
100-mg and 150-mg controlled release capsules
The only antiarrhythmic that offers a specific q12h dosage schedule
☐ Convenient dosage schedule
☐ Enhanced patient compliance
☐ The continuous efficacy you expect
The most commonly seen side effects from disopyramide phosphate are anticholinergic, and the most severe are due to its negative inotropic properties.
Please see the brief summary of prescribing information on the following page
SEARLE



Norpace® CR

(disopyramide phosphate)

100-mg and 150-mg controlled release capsules

Before prescribing, please consult current complete prescribing information, a summary of which follows: **Indications:** For suppression and prevention of recurrence of the following cardiac arrhythmias: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Norpace CR should not be used initially if rapid establishment of disopyramide plasma levels is desired. Oral disopyramide phosphate has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Norpace or Norpace CR may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace or Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace or Norpace CR, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace or Norpace CR should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace or Norpace CR should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patients should be monitored closely, and discontinuation of Norpace or Norpace CR considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace or Norpace CR with other Type 1 antiarrhythmic agents and/or propranolol should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace or Norpace CR should be reduced. If the block persists, continuation of Norpace or Norpace CR must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi-, or trifascicular block requires discontinuation of drug unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, disopyramide phosphate should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken. In patients with a family history of glaucoma, intraocular pressure should be measured before initiating Norpace or Norpace CR therapy. Precautions:** Patients with atrial flutter or fibrillation should be digitalized prior to Norpace or Norpace CR administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace or Norpace CR is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of disopyramide phosphate. Therefore, a loading dose of Norpace should not be given to such patients, and initial dosage and subsequent dosage adjustments should be made under close supervision. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs for overdosage. Norpace CR is not recommended for patients with severe renal insufficiency. Concomitant administration of disopyramide phosphate with phenytoin or other hepatic enzyme inducers may cause lower disopyramide plasma levels. Antiarrhythmic drugs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced in patients with hyperkalemia. Therefore, potassium abnormalities should be corrected before starting Norpace or Norpace CR therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood. **Norpace has been reported to stimulate contractions of the pregnant uterus.** Use of Norpace or Norpace CR in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace or Norpace CR on the fetus during delivery or on the course of labor and delivery are unknown. **Adverse Reactions:** Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, 'dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported, as have fever, respiratory difficulty, thrombocytopenia, and gynecomastia. **Dosage and Administration:** Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg/day given in divided doses: q6h for Norpace and q12h for Norpace CR. **See current complete prescribing information for dosage recommendations.**

CORONARY HEART DISEASE

221 Coronary Reperfusion and Bezold-Jarisch Reflex (Bradycardia and Hypotension)

PAOLO ESENTE, ALESSANDRO GIAMBARTOLOMEI, GOFFREDO G. GENSINI, and CARLOS DATOR

The occurrence of the Bezold-Jarisch reflex, a cardioinhibitory reflex characterized by bradycardia and hypotension, was observed in 20 of 92 patients undergoing intracoronary thrombolysis in a very early phase of acute myocardial infarction. Right coronary artery recanalization was frequently (65%) followed by the Bezold-Jarisch reflex with a close temporal relation. In only 22% of patients with a nonoccluded or nonrecanalized right coronary artery did hypotension and bradycardia develop. In 1 instance only, the reflex was elicited by recanalization of the left anterior descending coronary artery. Postural changes, atropine, or temporary pacing was successfully used in all but 1 patient, who required additional therapy. Left ventricular function studies 1 to 12 weeks after recanalization failed to show a better recovery among patients in whom the Bezold-Jarisch reflex developed. A cardioinhibitory reflex is frequently induced by reperfusion of the inferoposterior left ventricular wall. However, it does not appear to be a reliable predictor of myocardial salvage.

225 Natural History of Patients With Single-Vessel Disease Suitable for Percutaneous Transluminal Coronary Angioplasty

MARK A. HLATKY, ROBERT M. CALIFF, YIHONG KONG, FRANK E. HARRELL, Jr., and ROBERT A. ROSATI

To permit comparison of percutaneous transluminal coronary angioplasty (PTCA) with conventional therapy, the clinical outcome of patients who presented before PTCA became available, but who would be suitable for PTCA if they presented today, was established. One hundred ten patients were judged suitable for PTCA after review of their coronary angiograms. Five years after catheterization, 97% of the medically treated patients were alive, and 85% had not had a myocardial infarction. Fifty-six patients eventually underwent coronary bypass surgery. Five years after surgery, 91% were alive and 87% had not had a myocardial infarction. Functional capacity and employment were well maintained during follow-up. There were no significant differences in outcome between patients treated medically and those treated surgically. These data indicate that patients with single-vessel disease suitable for PTCA have an excellent prognosis when revascularization is reserved for those whose symptoms were not controlled adequately by medical therapy.

230 Detrimental Effect of Propranolol in Patients With Coronary Arterial Spasm Countered by Combination With Diltiazem

PIERRE Y. TILMANT, JEAN M. LABLANCHE, FRANÇOIS A. THIEULEUX, BERNARD A. DUPUIS, and MICHEL E. BERTRAND

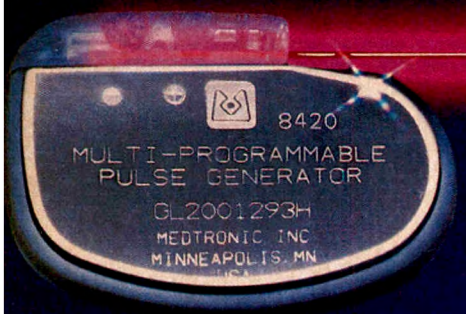
Eleven patients with documented coronary spasm were entered prospectively in a study with 4 phases of 2 days each: (1) control, (2) diltiazem or propranolol (mean 225 + 75 mg/day), (3) propranolol or diltiazem (360 mg/day), and (4) propranolol and diltiazem. The effects of the drugs were assessed by the detection of ischemic electrocardiographic episodes (24-hour electrocardiographic monitoring) and provocative tests with ergonovine. During the period of treatment with propranolol, the number and the duration of attacks increased and provocative tests had positive results in all patients. Diltiazem completely abolished spontaneous episodes, but 6 of 11 patients remained sensitive to the administration of ergonovine. The association of the 2 drugs leads to a disappearance of ischemic episodes. In conclusion, the propranolol is ineffective in patients with coronary artery spasm; it can be used in combination with diltiazem, but without any advantage over diltiazem alone.

SPECTR

THE WORLD'S MOST PRESCRIBED PACEMAKER

THRESHOLD MARGIN TEST.

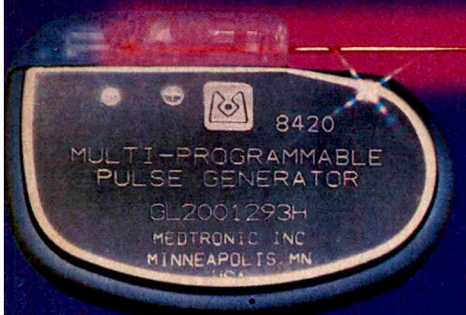
Insure adequate threshold safety margins—even over the telephone



A 66 year old female patient on vacation calls your office long distance for a routine pacer check. Are the pacing pulses sufficient to stimulate her heart? Here's how the unique Spectrax SXT™ **threshold margin test** helps you. Your patient simply positions the magnet she carries over her pacemaker and the Spectrax SXT automatically performs the test. Energy in the 3rd of 3 pulses emitted at 100 **ppm** is reduced 25% with no loss of capture, indicating an adequate safety margin. Long distance diagnosis is complete and your patient enjoys peace of mind.

AUTOMATIC THRESHOLD MEASUREMENT.

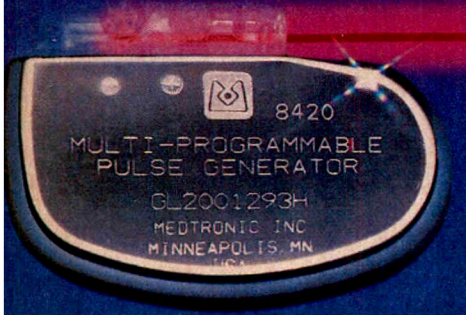
Determine pacing energy levels—fast.



You suspect loss of capture in a 62 year old male referral patient. What energy levels are needed for effective pacing stimulation of his heart? The exclusive **threshold measurement** built into his Spectrax SXT™ pacemaker gives you the answers fast. With the advanced Medtronic® CENSYS™ programmer, **automatic threshold measurement** is a simple pushbutton procedure. Reducing pulse width to the point of capture/loss tells you within 0.1 **ms** your patient's threshold. Restore original pulse width with no reprogramming needed and adjust to guarantee capture. Simple, convenient and electronically precise. That's Spectrax SXT's **automatic threshold measurement** feature.

PULSE GENERATOR BATTERY DEPLETION WARNING.

(EOL). 3 distinct warnings signal elective replacement.



Your 70 year old female patient has rushed to your office in alarm. During her routine pulse self-check test, she determined that her pacemaker had dropped 10% in rate. The implanted unit is a Spectrax SXT though, and you are able to reassure her. This rate change is simply a safeguard warning signalling elective replacement. Pulse width on the Spectrax SXT automatically increases to compensate for the gradual decline in battery voltage. She is in no danger of pacemaker battery failure or loss of capture. This fact is easily and visibly confirmed with Spectrax SXT's noteworthy telemetry which prints out battery status on command. In this case the print out has changed from **"Battery OK"** to **Elec. Replace Time!** Seeing is believing. You and your patient have several months in which to make her surgery decision. You can confidently relieve her anxiety.

Medtronic

Medtronic Implantable Pulse Generators and Leads

Intended Uses

Ventricular pacing using an implantable ventricular pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses). An atrial pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation disorders but with intact, functioning A-V conduction systems. Cardiac pacing using an implantable A-V sequential pulse generator is for long-term therapeutic control of heart rate in patients where restoration of A-V synchrony is indicated to improve cardiac output or to protect against arrhythmias related to sequence of cardiac impulse propagation.

Contraindications

There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate in patients with normal conduction systems. In certain patients with anomalies of the conduction system (WPW syndrome and related conditions), patients may be benefited or harmed by cardiac pacing. Therefore, electrophysiologic studies are required prior to therapeutic application of pacing. In addition, the patient's age and medical condition may dictate the particular pacing system and implantation procedure used by the physician.

Warnings

Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. See the specific precautions and warnings in the technical manuals included with the pulse generator.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

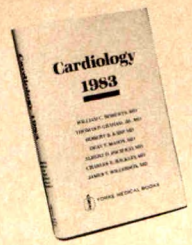
Cardiology 1983



The third issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

What is Cardiology 1983?

- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research
- A unique, cohesive summary of the state-of-the-art, **written**, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1983 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

234 **Long-Term Prognosis After First Q-Wave (Transmural) or Non–Q-Wave (Nontransmural) Myocardial Infarction: Analysis of 593 Patients**

RONALD J. KRONE, ELLEN FRIEDMAN, SAMER THANAVARO, J. PHILIP MILLER, ROBERT E. KLEIGER, and G. CHARLES OLIVER

Follow-up of 593 persons after hospital discharge for a first myocardial infarction was carried out for a mean of 4.7 years. Grouping patients by age, presence or absence of Q waves, and peak serum glutamic oxalacetic transaminase (SGOT) at the time of infarction established 4 groups with distinctly different survivorships. Of the patients who had had Q-wave infarctions, those with an SGOT level <240 IU/liter did better than did those with higher peak SGOT levels, at least for the first 6 months (mortality 3.1 versus 11%). The survivorship of patients who had had non–Q-wave (nontransmural) infarctions was excellent for 2 years (96.8% 2-year survival), but in the third year 12% of the patients older than 60 years of age at the time of their infarct died from cardiac causes, and each successive year an additional 12% of the original survivors died. The implications regarding follow-up strategy and therapy are discussed.

240 **Periods of Differing Mortality Distribution During the First Year After Acute Myocardial Infarction**

ELIZABETH A. GILPIN, JAMES A. KOZIOL, ERLING B. MADSEN, HARTMUT HENNING, and JOHN ROSS, Jr.

Mortality distributions during the first year after acute myocardial infarction (AMI) were analyzed for 3 large, geographically distinct populations using a special statistic to identify periods that exhibited different mortality distributions. The survival curves did not fit a single exponential, and the shapes of the 3 curves were similar. Changepoints in the distributions occurred at days 17, 23, and 24 in the 3 populations and at day 21 for the combined population. In the combined population, the point by which exactly 50% of deaths had occurred was day 19; 75% of the deaths occurred by day 100. These data further define the natural history after AMI and suggest periods appropriate for short- and longer-term interventions aimed at risk reduction.

245 **Validation of Technetium-99m Stannous Pyrophosphate Myocardial Scintigraphy for Diagnosing Acute Myocardial Infarction More Than 48 Hours Old When Serum Creatine Kinase-MB Has Returned to Normal**

HAROLD G. OLSON, KENNETH P. LYONS, SAMUEL BUTMAN, and KENNETH M. PITERS

To assess the feasibility of technetium-99m pyrophosphate scintigraphy in diagnosing acute myocardial infarction (AMI) after serum creatine kinase isoenzyme (CK-MB) has returned to normal, scintigrams were obtained in 107 patients with AMI at the time CK-MB was present, 37 ± 18 hours after the onset of AMI, and at the time CK-MB was absent, 106 ± 34 hours after the onset of AMI. When CK-MB was absent, the sensitivity using either a regional or a diffuse positive scintigram was 95% for transmural AMI and 65% for subendocardial AMI. The sensitivity using a regional positive scintigram was 82% for transmural AMI and 37% for subendocardial AMI. The sensitivity using a high-grade regional positive scintigram was 36% for transmural AMI and 11% for subendocardial AMI. The specificity was 70% for either a regional or a diffuse abnormality, 92% for a regional abnormality, and 100% for a high-grade regional abnormality. It is concluded that pyrophosphate scintigraphy is useful in confirming the diagnosis of AMI, particularly transmural, for an infarct >48 hours old when CK-MB has returned to normal. A positive scintigram with a high-grade regional abnormality is specific for a recent AMI and may contribute to establishment of the diagnosis when lactic dehydrogenase isoenzymes are inconclusive.

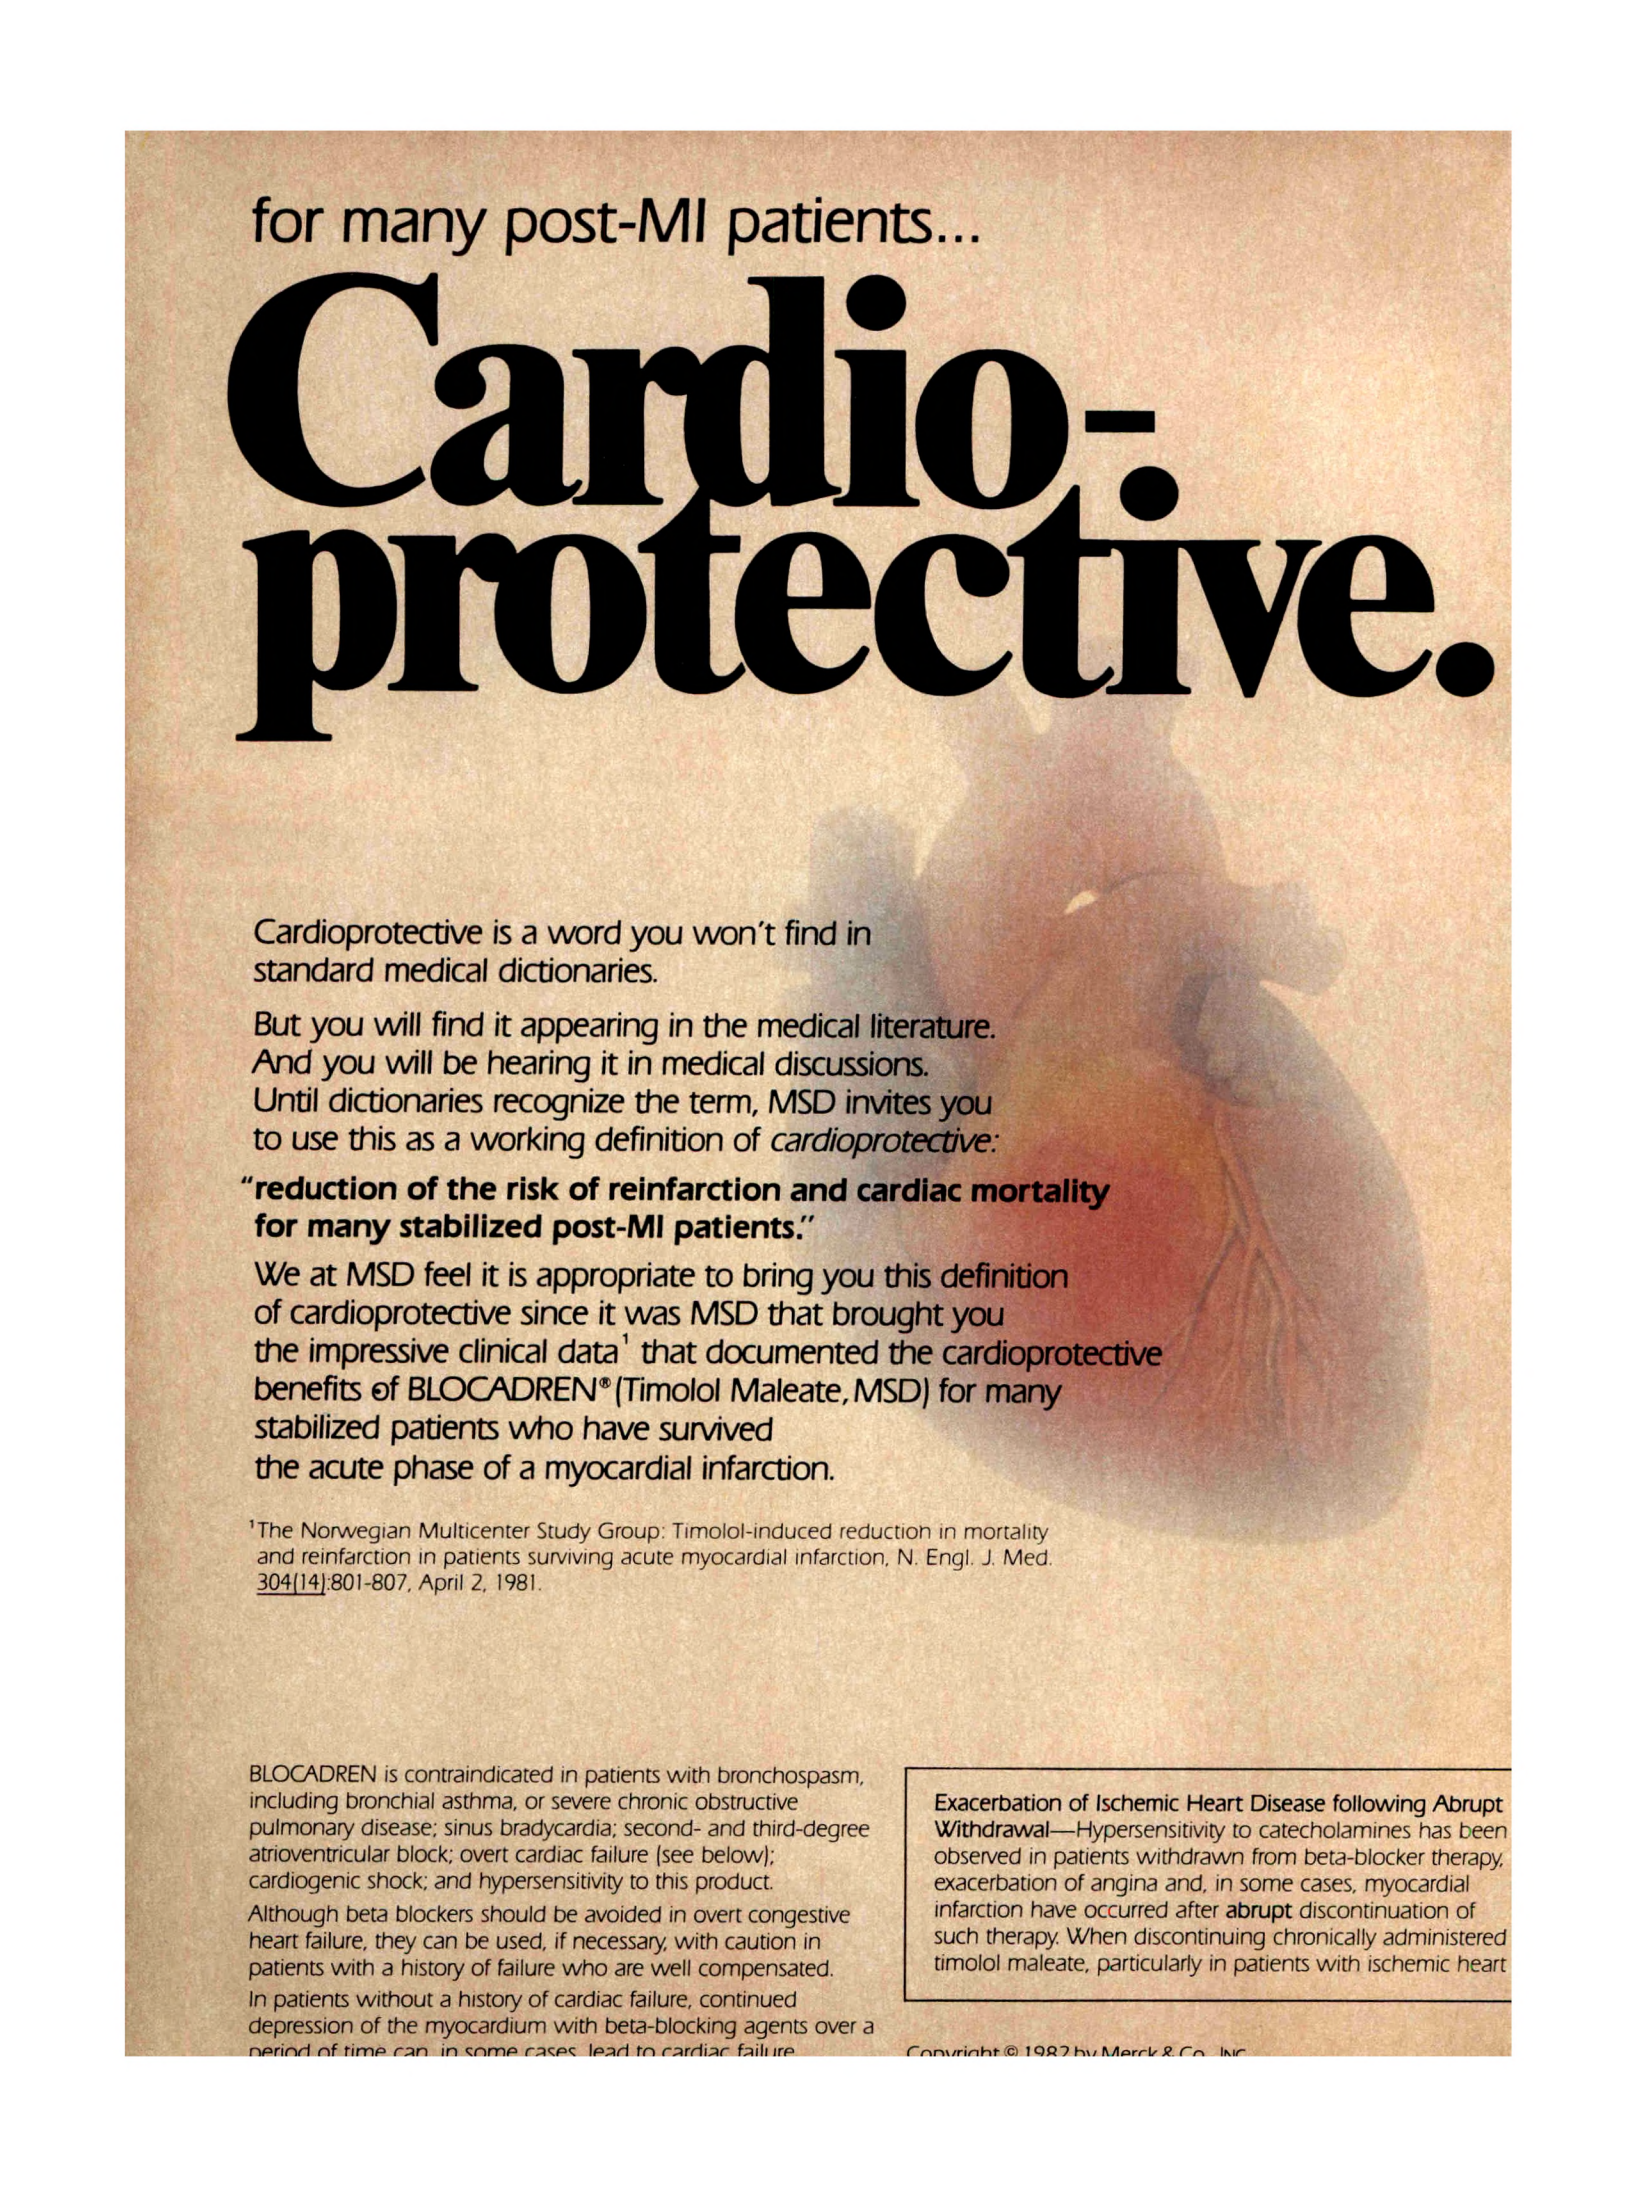
252 **Evaluation of Serial QRS Changes During Acute Inferior Myocardial Infarction Using a QRS Scoring System**

CHRISTINE I. ANDERSON, DAVID G. HARRISON, NANCY C. STACK, NANCY B. HINDMAN, RAYMOND E. IDEKER, SEBASTIAN T. PALMERI, RONALD H. SELVESTER, and GALEN S. WAGNER

The evolution of changes in the QRS complex during the 3 days after the onset of an initial inferior myocardial infarction was studied in 82 consecutive patients. Each patient's standard 12-lead electrocardiograms were assigned points (a QRS score) according to the absolute duration of the Q and R waves and the amplitude ratios of R-to-Q and R-to-S waves. This QRS score has been demonstrated to correlate ($r = 0.74$) with the anatomic extent of single inferior myocardial infarcts. By this system, 43 patients (53% of the study group) had an initial ECG that registered a score of 0 and developed QRS points only after admission. The QRS scores of 18 additional patients (22% of the study group) were observed to change after admission. Forty-nine score changes were noted on day 2 and 18 on day 3. All of these changes resulted in an increase in QRS score. Thus, there is a distinct pattern to the evolution of QRS changes during inferior infarction that results in sequential increases in a QRS score based upon electrocardiographic indicators of the extent of myocardial necrosis.

for many post-MI patients...

Cardio-protective.



Cardioprotective is a word you won't find in standard medical dictionaries.

But you will find it appearing in the medical literature. And you will be hearing it in medical discussions. Until dictionaries recognize the term, MSD invites you to use this as a working definition of *cardioprotective:*

"reduction of the risk of reinfarction and cardiac mortality for many stabilized post-MI patients."

We at MSD feel it is appropriate to bring you this definition of cardioprotective since it was MSD that brought you the impressive clinical data[1] that documented the cardioprotective benefits of BLOCADREN® (Timolol Maleate, MSD) for many stabilized patients who have survived the acute phase of a myocardial infarction.

[1]The Norwegian Multicenter Study Group: Timolol-induced reduction in mortality and reinfarction in patients surviving acute myocardial infarction, N. Engl. J. Med. 304(14):801-807, April 2, 1981.

BLOCADREN is contraindicated in patients with bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated.

In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy, exacerbation of angina and, in some cases, myocardial infarction have occurred after **abrupt** discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart

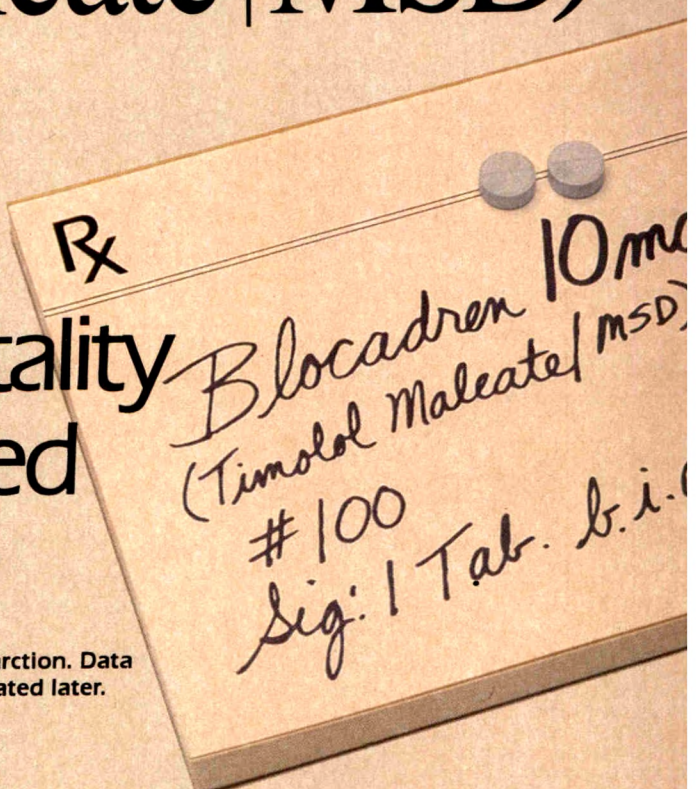
Blocadren®
(Timolol Maleate | MSD)

reduces the risk of reinfarction and cardiac mortality for many stabilized post-MI patients



Treatment should be initiated within 1 to 4 weeks after infarction. Data are not available as to whether benefit would ensue if initiated later.

disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

MSD
MERCK SHARP & DOHME

BLOCADREN®
(TIMOLOL MALEATE | MSD)

CONTRAINDICATIONS:

Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: *Impaired Hepatic or Renal Function*: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy—Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n=176) %	Placebo (n=168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
INTEGUMENTARY		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction†		Withdrawal‡	
	Timolol (n=945) %	Placebo (n=939) %	Timolol (n=945) %	Placebo (n=939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure—Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema—Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1
AV Block 2nd or 3rd degree	<1	<1	<1	<1
Sinoatrial Block	<1	<1	<1	<1
Cold Hands and Feet	8	<1	<1	0
Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

†When an adverse reaction recurred in a patient, it is listed only once.

‡Only principal reason for withdrawal in each patient is listed.

These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole*: extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular*: cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness; *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes; *Urogenital*: impotence, urination difficulties.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS); *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

257 Coronary and Left Ventricular Angiographic Anatomy and Prognosis of Survivors of First Acute Myocardial Infarction

ROBERT D. ABRAHAM, GARETH S. ROUBIN, PHILLIP J. HARRIS, LOUIS BERNSTEIN, and DAVID T. KELLY

To relate coronary anatomy and left ventricular (LV) function to prognosis, 197 of 269 consecutive survivors of a first myocardial infarction (MI) who were <60 years old underwent prospective cardiac catheterization a median of 2 weeks after admission and were followed up for a median 24 months (range 12 to 61). Seventy-two patients were excluded from angiography because of early death (9), severe noncoronary disease (44), MI complications (6), or patient refusal (13). The prevalence of multivessel disease was low (30%) and unrelated to the site of MI or the presence of Q waves but was higher in patients with previous angina pectoris ($p = 0.05$) or in those in Killip class II or III ($p = 0.02$). There were only 8 deaths from cardiac causes. The survival rate at 12 months was 97 ± 1% and at 24 and 36 months, 95 ± 2%. Nineteen patients underwent coronary revascularization surgery. Because the number of deaths was small, the differences in survival between patients with single or multivessel disease and normal or depressed ejection fractions failed to reach significance. Survivors of first MI <60 years old have a low prevalence of multivessel disease and a good prognosis.

261 Coronary Arterial Aneurysm Formation After Balloon Angioplasty

JAMES A. HILL, JAMES R. MARGOLIS, ROBERT L. FELDMAN, C. RICHARD CONTI, and CARL J. PEPINE

Previously described complications of percutaneous transluminal coronary angioplasty (PTCA) do not include coronary arterial aneurysm formation. Five patients with coronary arterial aneurysm formation at the site of PTCA are described. Aneurysms were found 11 days to 4 months after PTCA. Before PTCA, all patients were in New York Heart Association functional class III or IV and in 2 patients, myocardial infarctions with acute coronary occlusion were evolving. Evidence for intimal disruption or abrupt reocclusion was present in the other 3 patients after PTCA. Four of the 5 patients had angina at the time of the follow-up catheterization that identified the aneurysm from 11 days to 4 months after PTCA. Possible mechanisms of aneurysm formation and its relationship to healing are discussed.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

265 The Automatic Implantable Defibrillator: Local Ventricular Bipolar Sensing to Detect Ventricular Tachycardia and Fibrillation

ROGER A. WINKLE, STANLEY M. BACH, Jr., DEBRA S. ECHT, CHARLES D. SWERDLOW, MIR IMRAN, JAY W. MASON, PHILIP E. OYER, and EDWARD B. STINSON

The first generation automatic implantable defibrillator implanted in man reliably detected ventricular fibrillation and sinusoidal ventricular tachycardia, but failed to sense all nonsinusoidal ventricular tachycardias. To solve this problem, a new ventricular tachycardia detection scheme was developed using a local ventricular bipolar electrogram and electronic circuits using rate averaging and automatic gain control. This detection scheme was tested during electrophysiologic studies in 11 patients with ventricular tachycardia and fibrillation. All 22 episodes of induced ventricular tachycardia with a rate above the selected cutoff were detected after an average of 5.1 ± 1.8 seconds. Arrhythmia detection and signal quality in 9 patients who received automatic defibrillators using the new bipolar circuit were compared with the findings in 5 patients who previously received first generation units. The newer bipolar units had shorter and more uniform sense times (5.5 ± 1.4 versus 12.2 ± 7.1 seconds). It is concluded that malignant ventricular tachyarrhythmias can be accurately sensed using bipolar rate detection and that this system has significant advantages over the previously used detection scheme.

271 Effects of Oral Diltiazem in Paroxysmal Supraventricular Tachycardia

SAN-JOU YEH, HWAI-CHENG KOU, FUN-CHUNG LIN, JUI-SUNG HUNG, and DELON WU

The effects of oral diltiazem on induction and sustenance of paroxysmal supraventricular tachycardia were evaluated in 36 patients, 24 with atrioventricular (AV) reentrance incorporating an accessory pathway and 12 with AV nodal reentrance. Diltiazem prevented induction or sustenance of tachycardia in 20 of the 24 patients with AV reentrance, due to increased anterograde normal pathway refractoriness in 19 patients and increased retrograde accessory pathway refractoriness in 1 patient. It prevented induction or sustenance of tachycardia in 8 of the 12 patients with AV nodal reentrance, due to increased anterograde slow pathway refractoriness in 2 patients and increased retrograde fast pathway refractoriness in 6. Thus, oral diltiazem may be used as an alternative antiarrhythmic agent for prophylaxis of paroxysmal supraventricular tachycardia.

279 **Effect of Procainamide on Dispersion of Ventricular Refractoriness**

JAY A. SHECHTER, RUTH CAINE, TED FRIEHLING, PETER R. KOWEY, and

Ventricular arrhythmias after Q-T prolongation by drugs could result from a nonhom toriness (dispersion). Dispersion of effective refractory periods (ERP) was measur procainamide. Procainamide prolonged ERP in drive by an average of 30 ms ($p < 0$ 50 ms ($p < 0.001$). Procainamide did not alter measured dispersion (54 ± 16 to 44 ± to 47 ± 13 ms in drive). Polymorphic ventricular tachycardia (VT) was induced in 6 generally failed to reduce dispersion; less polymorphic tachycardia after procainam rowed dispersion. Polymorphic VT was not induced after procainamide in 2 patients sades de pointes caused by type I drugs. The mechanism of torsades was not expla toriness or by polymorphic VT initiated by premature beats after a type I drug.

283 **Exercise-Induced Bundle Branch Block**

VICTOR S. WAYNE, RICHARD L. BISHOP, LINDA COOK, and DAVID H. SPC

To investigate exercise-induced bundle branch block (BBB), clinical, electrocardiogr ic, scintigraphic, and follow-up data were analyzed in 16 patients, 11 with exercis Fourteen had a preexisting electrocardiographic abnormality—11 had either incom traventricular conduction delay. Heart rates of exercise BBB onset varied from 7(tients, onset and offset rates appeared to be related (within 8 beats/min). Of the 16 tery disease (CAD), 2 cardiomyopathy, 2 probable coronary spasm, 1 ventricular arr and 1 had no cardiac disease. Three patients had reversible thallium perfusion defe concurrent with development of exercise BBB. Three patients in whom exercise B a mean of 28 months of follow-up, 2 patients died of noncardiac causes and 1 had a tion. Thus, exercise-induced BBB primarily occurs in cardiac disease, mostly CAD; tate against CAD.

287 **Pacemaker-Mediated Tachycardias: A Rapid Bedside Technique for Induction**

PHILIP O. LITTLEFORD, R. CHARLES CURRY, Jr., KERRY M. SCHWARTZ, an

Thirty-one patients who underwent DDD pacemaker implantation were evaluated f loatrial conduction. Ventriculoatrial conduction was found in 17 patients using a sir tection of ventriculoatrial conduction was uniformly associated with pacemaker tachycardia was prevented by manipulation of the atrial refractory period. When ver present over the follow-up period, it was remarkably constant in duration but disapp failure or antiarrhythmic therapy.

292 **Intermittent Preexcitation in the Wolff-Parkinson-White Syndrome**

GEORGE J. KLEIN and SAJAD S. GULAMHUSEIN

The prevalence of intermittent preexcitation in 52 consecutive patients with Wolff was determined by reviewing electrocardiogram, ambulatory monitoring and treadr electrophysiologic testing to determine the electrophysiologic correlates of this p tients, 50% had intermittent loss of the delta wave. These patients had longer effect accessory pathway (356 ± 114 vs 295 ± 29 ms, $p < 0.05$) and longer shortest cycle terograde conduction (426 ± 171 vs 291 ± 63 ms, $p < 0.02$) than their counterpa wave. During atrial fibrillation, 85% of the patients with intermittent loss of the delta vals between preexcited beats >250 ms, versus 50% of patients with constant pre data support the hypothesis that intermittent loss of the delta wave suggests a beni atrial fibrillation.

SYSTEMIC HYPERTENSION

297 **Malignant Hypertension in Women Aged 15 to 44 Years and Its Relation to Cig Oral Contraceptives**

DIANA B. PETITTI and ARTHUR L. KLATSKY

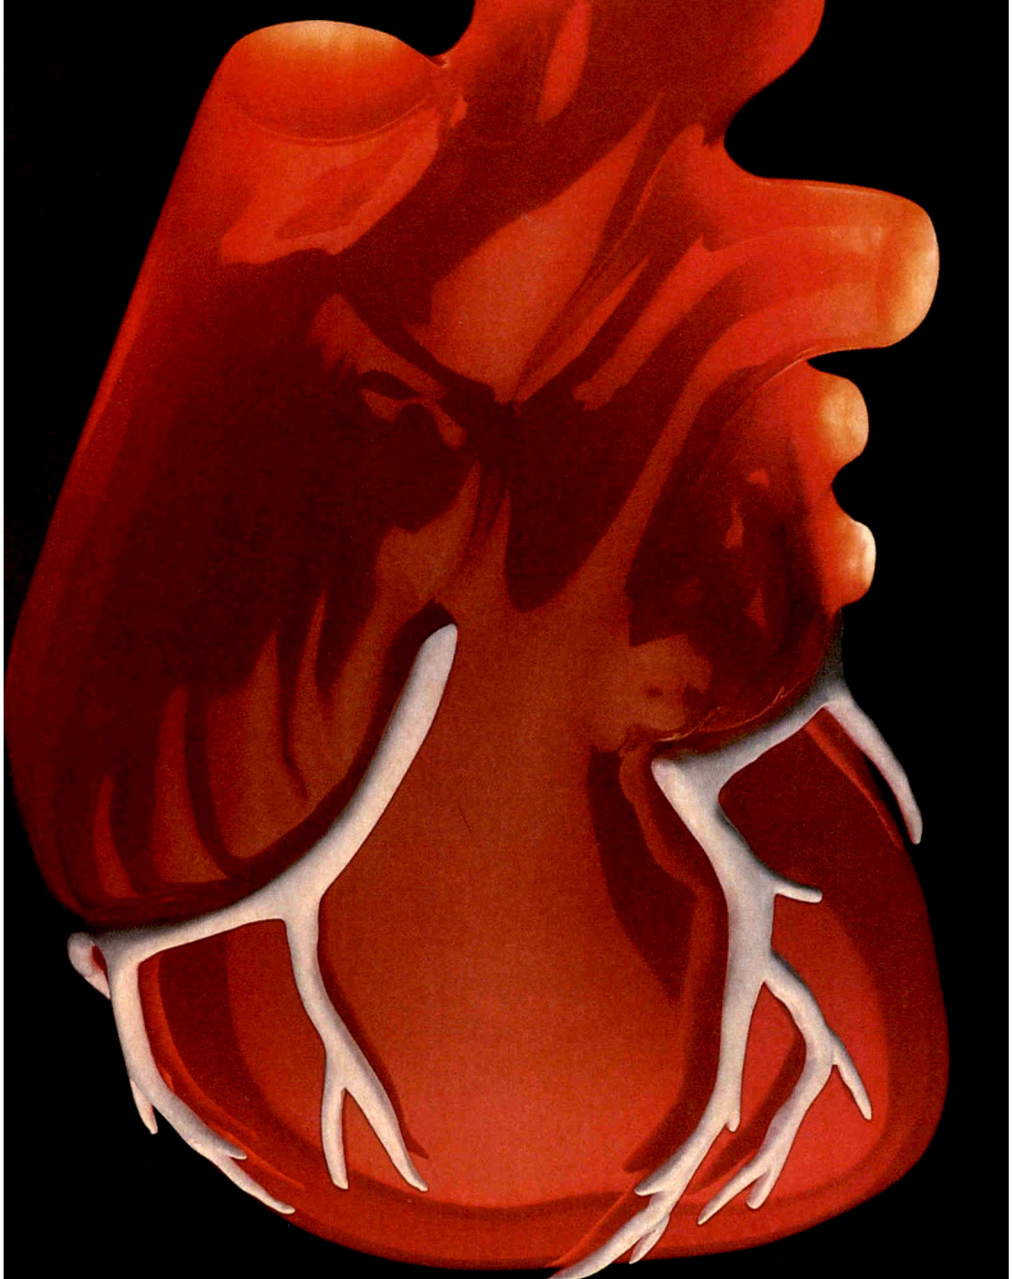
Announcing a major advance
in cardiovascular therapy

New CARDIZEM™ (diltiazem HCl)

CALCIUM CHANNEL BLOCKADE
from Marion Laboratories



Potent coronary vasodilation with a
distinctive hemodynamic profile

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

INCREASES EXERCISE TOLERANCE, REDUCES ANGINAL FREQUENCY WITH A LOW INCIDENCE OF SIDE EFFECTS

CARDIZEM™ (diltiazem HCl) produces changes in cardiovascular hemodynamics and coronary blood flow that are of benefit in myocardial ischemia.

These changes provide effective therapy with a low incidence of side effects.

Indications

(1) Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm.

(2) Cardizem is indicated in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

ANTIANGINAL MECHANISM OF ACTION

- Produces relaxation of coronary vascular smooth muscle
- Dilates both large and small coronary arteries at drug levels that cause little or no negative inotropic effect
- Produces dose-dependent decreases in peripheral resistance
- Resting heart rate is usually unchanged or slightly reduced

Reduces the pressure/rate product for any given work load in patients with effort-associated angina

3, Marion Laboratories, Inc.

CARDIZEM™ (diltiazem HCl) offers a distinctive profile of effects

(1) Vascular smooth-muscle relaxation with a potent effect on the coronary arteries.[1]

(2) Mild effect on afterload reduction.

(3) In normotensive patients at rest, recommended dosage levels producing coronary vasodilation result in only a mild reduction in diastolic blood pressure and no change in heart rate.

(4) At submaximal exercise, it causes a reduction in heart rate and mean blood pressure compared with placebo, thus reducing myocardial oxygen demand and permitting patients to exercise significantly longer.

(5) Increases coronary blood flow.

(6) Little or no negative inotropic effect at recommended doses while providing a powerful inhibition of coronary artery spasm.

(7) A positive effect on left ventricular function in patients with reduced left ventricular ejection fraction.[2]

(8) Increases ejection fraction at both submaximal and maximal exercise. Exercise ejection fraction is especially increased in patients with poor ventricular function.[3]

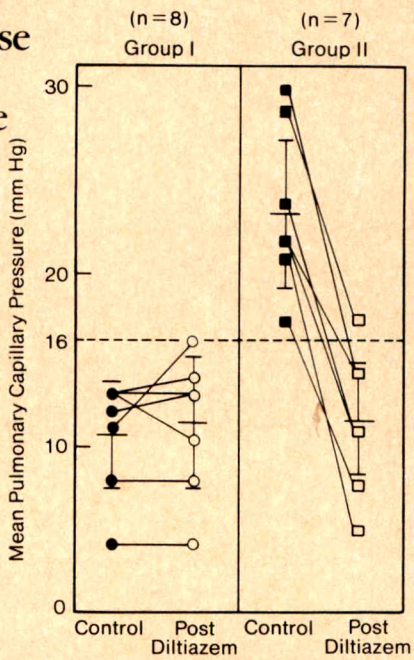
While Cardizem tends to prolong AV conduction,* only rarely has there been an increase in PR intervals outside of normal limits.

*See Contraindications and Warnings.

CARDIZEM™ (diltiazem HCl) tends to normalize stress-induced increases in pulmonary capillary pressure (PCP)

The effect of a single 120-mg† dose of Cardizem was evaluated on symptom-limited upright exercise in 15 patients with effort angina.[4]

†It should be noted that this study employed a single 120-mg dose of diltiazem for hemodynamic measurement purposes. The approved maximum dose for Cardizem is 240 mg given in divided doses, three to four times daily.



CHANGE IN FILLING PRESSURE AT MAXIMAL EXERCISE[4]

Patients with control PCPs in normal range at maximal exercise showed little change in these values following diltiazem (Group I). Patients with markedly elevated control PCPs at maximal exercise (>16 mm Hg) showed dramatic reductions in these values following diltiazem (Group II).

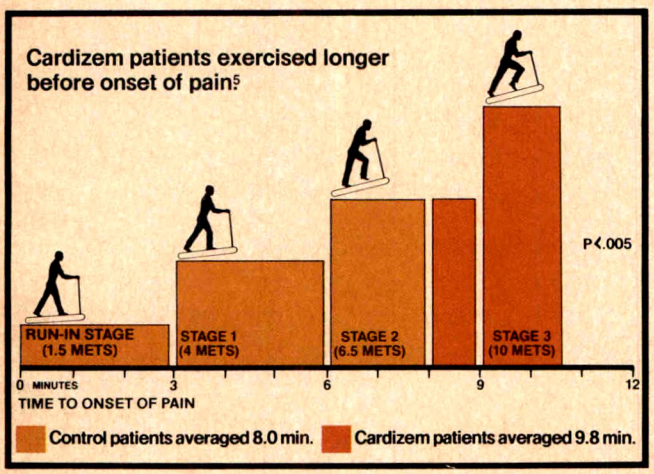
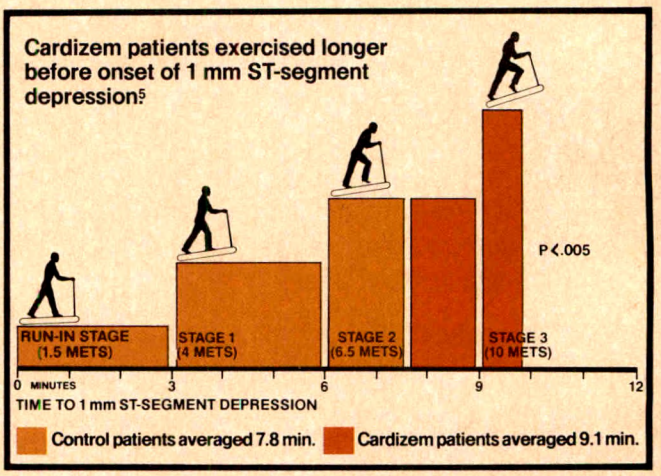
EXCELLENT CLINICAL RESPONSE TO CARDIZEM™ (diltiazem HCl) IN THE MANAGEMENT OF CLASSIC EFFORT ANGINA

CARDIZEM™ (diltiazem HCl) allows angina patients to significantly prolong exercise tolerance, even in demanding Bruce protocol exercise tests[5] (n=15)*





Protocol:

A Bruce protocol with a run-in stage was used. Each stage lasts three minutes.

Succeeding stages represent such an increase in speed and slant of the treadmill that each minute spent in a succeeding stage represents a highly significant increase in metabolic equivalents (METS). For example, METS expenditure in run-in stage of the protocol (0 to 3 min) is 1.5. METS expenditure of stage 1 (3 to 6 min) is 4.0. Stage 2 (6 to 9 min) expenditure is 6.5, and stage 3 (9 to 12 min) is 10.

The study[5,6] was double-blind, randomized, triple cross-over comparing diltiazem with placebo, lasting 7 weeks.

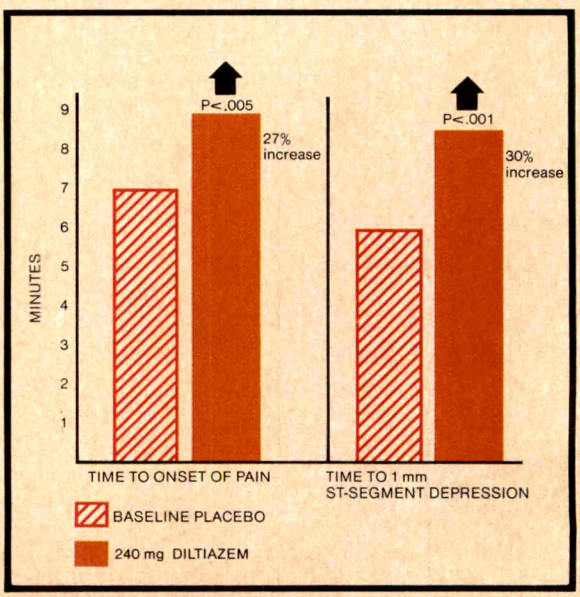
*This study is a report from one center in a multicenter study.

CARDIZEM™ (diltiazem HCl) produced marked angina improvement in multicenter study[6]

- 27% increase in time to onset of pain
- 30% increase in time to ST-segment depression



RESULTS OF 57 PATIENTS EVALUATED IN A MULTICENTER STUDY[6]

CARDIZEM™ (diltiazem HCl) PRODUCED SIGNIFICANT DECREASE IN EFFORT ANGINA ATTACKS COMPARED WITH PLACEBO IN 63-PATIENT DIARY STUDY[7]

Cardizem therapy resulted in a mean reduction of 5.3 attacks per week during weeks 7 and 8, compared with a mean reduction with placebo of 2.0 attacks per week.

During weeks 9 and 10, Cardizem therapy resulted in a mean reduction of approximately 5.9 attacks per week compared with a mean reduction of 2.5 attacks per week with placebo.

41% TO 68% REDUCTION IN FREQUENCY OF PRINZMETAL'S VARIANT ANGINA ATTACKS WITH CARDIZEM™ (diltiazem HCl)[8]

Mean attack rate during 120-mg/day dosage period was reduced 41% from baseline period. In 240-mg/day phase, decrease with Cardizem was 68%. This shows a positive dose-related response.

75% reduction in attack rate reported in 13-patient, cross-over, placebo-controlled study[1]

71% reduction in attack rate reported in 11-patient, cross-over, placebo-controlled study[9]

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

LOW INCIDENCE OF SIDE EFFECTS WITH CARDIZEM™ (diltiazem HCl)

In placebo-controlled trials conducted in the United States, the incidence of adverse reactions reported during Cardizem therapy was not greater than that reported during placebo therapy.

Those adverse reactions reported most frequently with CARDIZEM™ (diltiazem HCl) have been:

- Nausea 2.7%
- Swelling/edema 2.4%
- Arrhythmia 2.0%
- Headache 2.0%
- Rash 1.8%
- Fatigue 1.1%

In many cases, the relationship to Cardizem has not been established.

Other reactions infrequently reported (<1.0%) during supervised trials were:

- Cardiovascular: Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart
- Central Nervous System: Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations
- Gastrointestinal: Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis
- Dermatologic: Pruritus, petechiae, urticaria
- Other: Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain

Of those adverse reactions reported, the most severe were:
A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of Cardizem.

Experience in 959 patients taking oral doses of Cardizem resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

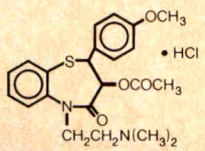
In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during Cardizem therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

PROFESSIONAL USE INFORMATION

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanism of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (4 of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem t.i.d. of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely, and enzymes were nearly normal a week after cessation of treatment. No rechallenge was carried out, but the patient had no evidence of viral hepatitis and received no other drugs but isosorbide dinitrate.

   No other similar liver injury has been reported in clinical trials, but marketing experience in Europe has resulted in a rechallenge-confirmed instance of hepatocellular injury. However, it should be noted that there have been further episodes of raised transaminases in the absence of diltiazem in this patient, so that the relationship to diltiazem of the abnormalities is not completely clear. Other instances of transaminase elevation have been reported in Europe, but their relationship to drug is uncertain.

PRECAUTIONS

General. CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect of diltiazem on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-blockers or digitalis is currently being investigated in well-controlled studies.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. Experience with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), and fatigue (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of presentation corresponds to the relative frequency of occurrence.

Cardiovascular:	Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart.
Central Nervous System:	Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations.
Gastrointestinal:	Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis.
Dermatologic:	Pruritus, petechiae, urticaria.
Other:	Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and safety of dosages exceeding 240 mg per day are currently being investigated. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents.

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

women of these ages per year. Four women had underlying renal disease. Of the other 11 women, all used oral contraceptives, smoked cigarettes, or both. Nine were white; 6 women had normal blood pressure in the 24 months before hospitalization.

CONGESTIVE HEART FAILURE

299 Determinants of Circulatory Response to Intravenous Hydralazine in Congestive Heart Failure

JOHN R. WILSON, MARTIN ST. JOHN SUTTON, J. SANFORD SCHWARTZ, NANCY FERRARO, and NATHANIEL REICHEK

The factors that determine the circulatory response to hydralazine were investigated in 28 patients with chronic left ventricular (LV) dysfunction. Hemodynamic data and echocardiographic LV end-diastolic dimension were correlated with the response to 20 mg of intravenous hydralazine and to a dose titrated to reduce systemic resistance (SVR) ≥20%. Hydralazine, 20 mg, decreased SVR (from 23 ± 8 to 18 ± 8 U [$p < 0.01$]) and increased cardiac index (from 2.0 ± 0.5 to 2.5 ± 0.6 liters/min/m^2 [$p < 0.01$]) and stroke work index (SWI) (from 21 ± 11 to 24 ± 9 g·m/m^2 [$p < 0.05$]). Titrating the dose increased the cardiac index further to 2.7 ± 0.6 liters/min/m^2 and SWI to 32 ± 9 g·m/m^2. The change in SVR produced by 20 mg of hydralazine correlated only with initial SVR ($r = 0.53$). The percent change in SWI produced by 20 mg of hydralazine correlated directly with end-diastolic wall stress ($r = 0.69$) and pulmonary wedge pressure ($r = 0.43$) and inversely with SWI ($r = -0.49$). Similar correlations were observed when the dose of hydralazine was titrated. The response to hydralazine did not correlate with LV end-diastolic dimension or right atrial pressure. Thus, the vascular response to moderate doses of hydralazine is related to initial SVR, whereas LV pump response is related to the level of initial LV pump dysfunction.

304 Amrinone Therapy for Congestive Heart Failure in Outpatients With Idiopathic Dilated Cardiomyopathy

CARL V. LEIER, KAREN DALPIAZ, PATRICIA HUSS, JAMES B. HERMILLER, RAYMOND D. MAGORIEN, THOMAS M. BASHORE, and DONALD V. UNVERFERTH

Chronic dosing of amrinone in 13 patients with moderate to severe congestive heart failure effected a modest, but significant, improvement in exercise tolerance compared with a comparable control group. Amrinone did not improve functional classification, noninvasive indexes of LV function or exercise ejection fraction above control values. All patients who received amrinone experienced at least 1 symptom-related or laboratory-detected side effect.

VALVULAR HEART DISEASE

309 Echocardiographic Evaluation of Porcine Bioprosthetic Valves: Experience With 309 Normal and 59 Dysfunctioning Valves

MOHSIN ALAM, JEFFREY B. LAKIER, SOL D. PICKARD, and SIDNEY GOLDSTEIN

To determine the clinical value of echocardiography in the evaluation of porcine bioprosthetic valves, we analyzed adequate-quality echocardiographic studies of 309 normal and 59 dysfunctioning valves. Valve dysfunction resulted from spontaneous cusp degeneration in 39 (34 valve regurgitations, 5 stenoses), infective endocarditis in 12, paravalvular regurgitation in 5, and regurgitation of redundant cusps, mitral valve thrombi, and aortic stent stenosis in 3 others. Echocardiographic findings were correlated with pathology for 45 of 59 dysfunctioning valves. Echocardiographic abnormalities were demonstrated in 41 of 59 (69%) dysfunctioning valves. A systolic mitral or diastolic aortic valve fluttering was diagnostic of a regurgitant valve due to torn or unsupported cusp margin and was observed in 28 of 34 (82%) regurgitant valves. Echocardiographic cusp thickness of ≥3 mm correctly identified all regurgitant and stenotic valves with gross anatomic evidence of cusp thickening or calcific deposits. Echocardiographic valve abnormalities were observed in only 4 of 12 patients with infective endocarditis and 1 of 5 with paravalvular regurgitation.

316 Abnormal Cardiovascular Regulation in the Mitral Valve Prolapse Syndrome

F. ANDREW GAFFNEY, BRUCE C. BASTIAN, LYNDA B. LANE, W. FRED TAYLOR, JURETA HORTON, JAMES E. SCHUTTE, ROBERT M. GRAHAM, WILLIAM PETTINGER, and C. GUNNAR BLOMQVIST, *With the technical assistance of* WILLIE E. MOORE, Jr.

Studies of patients with the mitral valve prolapse (MVP) syndrome suggest autonomic nervous system dysfunction, but a precise definition of mechanisms is lacking. In this study, supine and standing heart rate, blood pressure, cardiac output, oxygen consumption, plasma catecholamine levels, and plasma volume were measured in 23 women with MVP and in 17 normal control subjects. An analysis of the hemodynamic state at rest and the

NEW TABLET DESIGN 0.5, 1.0 and 2.0 mg

Brief Summary of Prescribing Information.

Indications and Usage: Management of anxiety disorders or short-term relief of symptoms of anxiety or anxiety associated with depressive symptoms. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation. Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions. Observe usual precautions with impaired renal or hepatic function. Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component. Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (about 6 times maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatrics requires caution and frequent monitoring for symptoms of upper G.I. disease. Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug. In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® (IV) for (lorazepam) Anxiety

DOSAGE: Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.

HOW SUPPLIED: 0.5, 1.0 and 2.0mg tablets.

postural responses revealed 2 distinct subgroups of patients; those with a normal heart rate but increased vasoconstriction (Group I, n = 10) and those with orthostatic tachycardia (Group II, n = 13). The supine heart rate in Group I patients and control subjects was virtually identical, 78 ± 3 and 79 ± 2 beats/min, respectively, compared with Group II patients, who had a heart rate (supine) of 97 ± 3 beats/min. Estimated total blood volumes were lowest in Group I patients, intermediate in Group II patients, and highest in control subjects ($p < 0.05$). After standing for 5 minutes, patients had a higher mean plasma epinephrine value, diastolic blood pressure (81 ± 2 versus 74 ± 3 mm Hg, $p < 0.05$) and peripheral resistance (1,878 ± 114 versus 1,414 ± 92 units, $p < 0.01$), wider calculated arteriovenous oxygen difference (6.7 ± 0.4 versus 5.3 ± 0.5 units, $p < 0.05$), and lower stroke volume index (26 ± 2 versus 33 ± 2 units, $p < 0.01$) than did the control subjects. Cardiac output was normal in Group II patients but reduced in the Group I patients, who demonstrated marked vasoconstriction. No patient had evidence of a "hyperkinetic" circulatory state. These symptomatic patients with MVP with subnormal stroke volumes maintained arterial pressure with either tachycardia or vasoconstriction. Increased plasma catecholamine levels were associated with a reduced blood volume. A cycle of decreased forward stroke volume, vasoconstriction, and blood volume contraction appears to be present.

CARDIOMYOPATHY

321 Noncardiovascular Findings Associated With Heart Disease in the Idiopathic Hypereosinophilic Syndrome

JOHN B. HARLEY, ANTHONY S. FAUCI, and HARVEY R. GRALNICK

Endomyocardial fibrosis is a major complication of the idiopathic hypereosinophilic syndrome. The noncardiovascular findings from a group of 50 patients are described that differentiate those in whom overt heart disease develops from those who remain free of heart disease. Patients with the idiopathic hypereosinophilic syndrome and heart disease are more likely to have characteristics of a myeloproliferative disorder, to be male, and to carry the Bw44 histocompatibility locus antigen. Patients who remain free of heart disease are more likely to have characteristics of an allergic disease and to be female. These results should help to identify patients at risk for the development of overt heart disease in the idiopathic hypereosinophilic syndrome.

CONGENITAL HEART DISEASE

325 Two-Dimensional Echocardiographic Assessment of Surgically Closed Ventricular Septal Defect

JOSE L. ANDRADE, WALTER SERINO, MARC de LEVAL, and JANE SOMERVILLE

In this study, 120 patients operated on for closure of a ventricular septal defect (VSD) were assessed echocardiographically. Echocardiographic findings of intact ventricular septum (VS) or residual shunt were correlated with angiographic findings in 30 patients and with clinical signs in 90 patients. Apart from minute shunts not detected echocardiographically and a few persistent small "drop-outs," probably due to peripatch edema or malalignment of the VS, wrongly interpreted as residual shunt, 2-dimensional echocardiography was a reliable noninvasive technique for detecting significant residual shunt and intact VS after surgical closure of VSD.

330 Postmortem Digoxin Tissue Concentration and Organ Content in Infancy and Childhood

ALOIS R. HASTREITER and RONALD L. VAN DER HORST

Postmortem tissue samples from 36 infants and children were analyzed for digoxin concentration. Dosage, duration and mode of administration were evaluated. Blood and tissue levels were generally higher in small infants than in older children and adults. Although toxicity was not studied, based on the therapeutic distributions observed, blood, liver, myocardium and probably skeletal muscle were felt to be the best markers for the evaluation of toxicity. Renal tissue was not considered reliable because of marked variability of digoxin concentration. Maximal therapeutic concentrations were twice as high in some tissue samples of premature and full-term neonates than in those from older children.

336 Masked Subaortic Stenosis in Ostium Primum Atrial Septal Defect: Recognition and Treatment

RHONDA S. LAPPEN, ALEXANDER J. MUSTER, FAROUK S. IDRISS, THOMAS W. RIGGS, MICHEL ILBAWI, MILTON H. PAUL, SAROJA BHARATI, and MAURICE LEV

Severe subaortic stenosis may be masked hemodynamically in ostium primum defect because of left ventricular systolic regurgitation into the right and left atria and a mobile cleft septal mitral leaflet. Such potential stenosis can be recognized morphologically by angiography and echocardiography before corrective surgery. Five patients who demonstrated subaortic pressure gradients (mean 56 mm Hg) postoperatively had characteristic systolic narrowing of the left ventricular outflow tract (goose-neck deformity), whereas goose-neck deformity narrowing is observed only during diastole in a typical case of ostium primum defect. This outflow narrowing is a re-

VENT. LEAD
AVIUS
Model 263-01
Intermedics Inc.
FREEPORT, TEXAS
DVI
DOO
VVI

HASSLE FREE PACING

AVIUS™ ELIMINATES MANY PROBLEMS ASSOCIATED WITH CURRENTLY AVAILABLE DUAL CHAMBER PRODUCTS AND OPTIMIZES PACING PERFORMANCE.

No more problems with:
Asynchrony
Crosstalk
Retrograde Conduction
Complex ECG's

AVIUS simply delivers good, reliable dual chamber performance. It's no wonder you can prescribe it with confidence.

AVIUS has more flexible programming capabilities than any other DVI pacemaker currently available.
With more prescription combinations to help you tailor pacing operation to individual patient needs.

AVIUS also has fewer post-op problems.
AVIUS is the DVI mode A-V sequential pacemaker that is inherently immune to many clinical complications experienced with other dual chamber products. Immune to the kinds of problems that force you to change modes.

AVIUS makes patient follow-up easier.
Interpretation of ECG recordings is less complex than with other more complex dual chamber products. And AVIUS offers you transtelephonic telemetry.

AVIUS is reliable.
Its circuitry is based on time-proven Intermedics circuitry. And it has the largest battery capacity of any available DVI pacemaker.

***AVIUS restores A-V synchrony* thus increasing cardiac output because it is a dual chamber pacing system.**

AVIUS practically eliminates pacemaker syndrome.

AVIUS. The pacemaker you can count on for hassle free pacing.
From Intermedics, the people with more clinical experience with dual chamber devices than any other company. For more information, contact your nearest Intermedics representative, or call us toll-free at 1-800-231-2330 (in Texas dial 1-800-392-3726).

Intermedics Inc.®

Our Business is Life.®

P.O. Box 617
Freeport, Texas 77541

INDICATIONS FOR USE: Implantable cardiac pulse generators may be indicated for long-term treatment of impulse formation or conduction disorders resulting in symptomatic bradyarrhythmias, and heart block unresponsive to drug therapy.

A-V sequential pacing is specifically indicated for treatment of conduction disorders that require restoration of both rate and atrio-ventricular synchrony. A-V sequential pacing may also be indicated for patients with extensive myocardial infarction with A-V block and sinus bradycardia.

CONTRAINDICATIONS AND SIDE EFFECTS: There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. Body rejection phenomena, local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism, and cardiac tamponade have been reported.

PRECAUTIONS: See the "Cautionary notes" section of the Physicians Manual for the Intermedics cardiac pluse generator to be implanted. Discussion includes Possible Complications, Environmental Hazards (electrocautery, diathermy, defibrillation, therapeutic radiation, home appliances, and industrial and special environments), and Effects of Drugs.

©Intermedics Inc. 1983

A41

sult of extensive excavation of the posterior smooth ventricular septum and an abnormally anterior and medial attachment of the mitral anulus that fills this gap in the septum. Additional obstruction may be produced by discrete fibrous ridges and poor mitral valve attachments. Surgical treatment includes resection of discrete obstructive elements, enlargement of the outflow tract and, rarely, replacement of the mitral valve.

341 **Mechanisms of Closure of Perimembranous Ventricular Septal Defect**

ROBERT H. ANDERSON, CORA C. LENOX, and JAMES R. ZUBERBUHLER

A series of hearts with an isolated perimembranous ventricular septal defect were examined for signs of partial closure by discrete anatomic structures. Twenty-six hearts (38%) showed evidence of partial occlusion, most often by tricuspid valve leaflets or structures derived from the tricuspid valve. Only 2 hearts showed any sign of closure by an aneurysm of the membranous septum. Perimembranous defects extending into the inlet or trabecular septum, or both, were commonly partially occluded; defects extending into the outlet septum never were.

346 **Two-Dimensional Echocardiographic Appearance of Complete Left-Sided Juxtaposition of the Atrial Appendages**

ALVIN J. CHIN, FREDRICK Z. BIERMAN, ROBERTA G. WILLIAMS, STEPHEN P. SANDERS, and PETER LANG

This report describes the 2-dimensional echocardiographic appearance of left-sided juxtaposition of the atrial appendages (JAA). Between January 1, 1978, and June 30, 1979, 2 infants had the diagnosis of left-sided JAA at autopsy. Review of the echocardiographic studies of these 2 patients revealed that the septum secundum was oriented posteriorly in the transverse view of the atria. From July 1979 to June 1981, prospective evaluation of all infants for the presence of this finding revealed it in 2 additional patients. Left-sided JAA was confirmed at surgery in 1 case and by selective right atrial angiography in the other. Thus, the diagnosis of left-sided JAA has important implications for both atrial baffle operations and for the Fontan procedure.

349 **Growth and Tissue Abnormalities in Young People With Cyanotic Congenital Heart Disease Receiving Systemic–Pulmonary Artery Shunts**

DAVID BAUM, REBECCA Q. BECK, and WILLIAM L. HASKELL

The effects of systemic–pulmonary artery shunts on growth, body composition and adipose tissue were studied in 29 children, aged 2 to 16 years, with cyanotic congenital heart disease. Sixteen of these patients received surgical shunts and 13 were unoperated. Postoperatively, all shunted patients were better oxygenated and were symptomatically improved. However, the groups were not significantly different in height, weight, lean body mass, total body fat, lean/fat ratio, cellular lipid content or total number of lipid-containing fat cells. Age at operation did not appear to influence the effects of surgery. These observations suggest that growth and certain measurements of tissue development were unaffected by surgical systemic–pulmonary artery shunts despite increased oxygenation and symptomatic improvement after operation.

353 **The Marfan Syndrome in Early Childhood: Analysis of 15 Patients Diagnosed at Less Than 4 Years of Age**

HENDRICA E. SISK, KENNETH G. ZAHKA, and REED E. PYERITZ, *With the technical assistance of* CATHY HENSLEY

To appreciate more completely the Marfan syndrome in early childhood, the clinical and echocardiographic features of 15 children diagnosed at <4 years of age were reviewed. Two children were lost to follow-up study, but in the 13 who were followed up, all had echocardiographic evidence of increasing aortic root dimension at a rate generally greater than predicted on the basis of increasing body surface area. Only 1 patient had aortic regurgitation and none required aortic surgery. All patients had mitral valve prolapse. Progressive mitral valve dysfunction was seen in 70% of patients and 4 required mitral valve replacement. These observations suggest that in children with Marfan syndrome, (1) aortic root dilatation is usually present early and serves as an objective indicator of the syndrome, and (2) mitral valve prolapse is common and mitral regurgitation, which may require valve replacement, is the leading cause of cardiovascular morbidity.

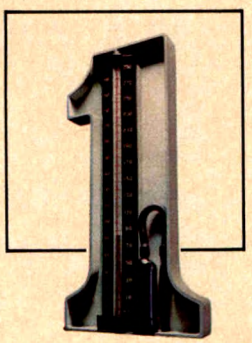
β_1

Today's answer in hypertension management.



One-tablet-a-day dosage

The starting dose—one 50 mg tablet a day—becomes the long-term maintenance dose for most patients.

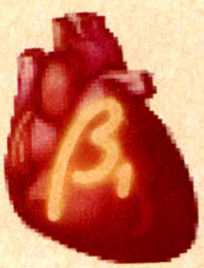
Time-consuming dosage adjustments are eliminated and optimal patient compliance is virtually assured.

Development of therapeutic tolerance has not been reported after long-term use.

...and cardioselectivity.*

A preferential effect on cardiac β_1 receptors rather than on bronchial or peripheral β_2 receptors provides an added margin of safety.

For a recent investigational study, the beta antagonist selected was TENORMIN "because of its cardioselectivity, its prolonged effectiveness over 24 hours, and its 'flat' dose-response curve...."[1]



*Cardioselectivity denotes a relative preference for β_1 receptors, located chiefly in cardiac tissue. This preference is not absolute.

Beta blocker therapy with both one-tablet-a-day dosage and cardioselectivity.

ONE TABLET A DAY

TENORMIN®

(atenolol)

See following page of this advertisement for brief summary of prescribing information.

STUART PHARMACEUTICALS

Today's answer in hypertension management.

TENORMIN® (atenolol)

A beta$_1$-selective blocking agent for hypertension.

INDICATIONS AND USAGE: TENORMIN (atenolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide-type diuretic.

CONTRAINDICATIONS: TENORMIN is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure: Sympathetic stimulation is necessary in supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, TENORMIN should be administered cautiously. Both digitalis and atenolol slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, TENORMIN therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents in patients with coronary artery disease, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Therefore, such patients should be cautioned against interruption of therapy without the physician's advice. Even in the absence of overt angina pectoris, when discontinuation of TENORMIN is planned, the patient should be carefully observed and should be advised to limit physical activity to a minimum. TENORMIN should be reinstated if withdrawal symptoms occur.

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASE SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, TENORMIN may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta, selectivity is not absolute the lowest possible dose of TENORMIN should be used, with therapy initiated at 50 mg and a beta$_2$-stimulating agent (bronchodilator) made available. If dosage must be increased, dividing the dose should be considered in order to achieve lower peak blood levels.

Anesthesia and Major Surgery: As with all beta-receptor blocking drugs it may be decided to withdraw TENORMIN before surgery. In this case, 48 hours should be allowed to elapse between the last dose and anesthesia. If treatment is continued, care should be taken when using anesthetic agents which depress the myocardium, such as ether, cyclopropane, and trichloroethylene.

TENORMIN, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects on the heart can be reversed by administration of such agents (eg, dobutamine or isoproterenol with caution—see OVERDOSAGE). Manifestations of excessive vagal tone (eg, profound bradycardia, hypotension) may be corrected with atropine (1-2 mg I.V.).

Diabetes and Hypoglycemia: TENORMIN should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected. TENORMIN does not potentiate insulin-induced hypoglycemia and, unlike nonselective beta blockers, does not delay recovery of blood glucose to normal levels.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (eg, tachycardia) of hyperthyroidism. Abrupt withdrawal of beta blockade might precipitate a thyroid storm; therefore, patients suspected of developing thyrotoxicosis from whom TENORMIN therapy is to be withdrawn should be monitored closely.

PRECAUTIONS: Impaired Renal Function: The drug should be used with caution in patients with impaired renal function (see DOSAGE AND ADMINISTRATION).

Drug Interactions: Catecholamine-depleting drugs (eg, reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with TENORMIN plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Should it be decided to discontinue therapy in patients receiving beta blockers and clonidine concurrently, the beta blocker should be discontinued several days before the gradual withdrawal of clonidine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Two long-term (maximum dosing duration of 18 or 24 months) rat studies and one long-term (maximum dosing duration of 18 months) mouse study, each employing dose levels as high as 300 mg/kg/day or 150 times the maximum recommended human dose, did not indicate a carcinogenic potential in rodents. Results of various mutagenicity studies support this finding.

Fertility of male or female rats (evaluated at dose levels as high as 200 mg/kg/day or 100 times the maximum recommended human dose) was unaffected by atenolol administration.

Animal Toxicology: Chronic studies performed in animals have revealed the occurrence of vacuolation of epithelial cells of Brunner's glands in the duodenum of both male and female dogs at all tested dose levels of atenolol (starting at 15 mg/kg/day or 7.5 times the maximum recommended human dose) and increased incidence of atrial degeneration of hearts of male rats at 300 mg but not 150 mg atenolol/kg/day (150 and 75 times the maximum recommended human dose, respectively).

USAGE IN PREGNANCY: Pregnancy Category C. Atenolol has been shown to produce a dose-related increase in embryo/fetal resorptions in rats at doses equal to or greater than 50 mg/kg or 25 or more times the maximum recommended human dose. Although similar effects were not seen in rabbits, the compound was not evaluated in rabbits at doses above 25 mg/kg or 12.5 times the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. TENORMIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not established to what extent this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving atenolol.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient. Frequency estimates were derived from controlled studies in which adverse reactions were either volunteered by the patient (U.S. studies) or elicited (eg, by checklist—foreign studies). The reported frequency of elicited adverse effects was higher for both TENORMIN and placebo-treated patients than when these reactions were volunteered. Where frequency of adverse effects for TENORMIN and placebo is similar, causal relationship is uncertain.

The following adverse-reaction data present frequency estimates in terms of percentages: first from the U.S. studies (volunteered side effects) and then from both U.S. and foreign studies (volunteered and elicited side effects):

U.S. STUDIES (% ATENOLOL-% PLACEBO):

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (0%-0.5%), postural hypotension (2%-1%), leg pain (0%-0.5%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (4%-1%), vertigo (2%-0.5%), light-headedness (1%-0%), tiredness (0.6%-0.5%), fatigue (3%-1%), lethargy (1%-0%), drowsiness (0.6%-0%), depression (0.6%-0.5%), dreaming (0%-0%)

GASTROINTESTINAL: diarrhea (2%-0%), nausea (4%-1%)

RESPIRATORY (See WARNINGS): wheeziness (0%-0%), dyspnea (0.6%-1%)

TOTALS U.S. AND FOREIGN STUDIES:

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (12%-5%), postural hypotension (4%-5%), leg pain (3%-1%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (13%-6%), vertigo (2%-0.2%), light-headedness (3%-0.7%), tiredness (26%-13%), fatigue (6%-5%), lethargy (3%-0.7%), drowsiness (2%-0.5%), depression (12%-9%), dreaming (3%-1%)

GASTROINTESTINAL: diarrhea (3%-2%), nausea (3%-1%)

RESPIRATORY (see WARNINGS): wheeziness (3%-3%), dyspnea (6%-4%)

MISCELLANEOUS: There have been reports of skin rashes and/or dry eyes associated with the use of beta-adrenergic blocking drugs. The reported incidence is small and, in most cases, the symptoms have cleared when treatment was withdrawn. Discontinuance of the drug should be considered if any such reaction is not otherwise explicable. Patients should be closely monitored following cessation of therapy.

POTENTIAL ADVERSE EFFECTS: In addition, a variety of adverse effects have been reported with other beta-adrenergic blocking agents, and may be considered potential adverse effects of TENORMIN (atenolol).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Fever, combined with aching and sore throat, laryngospasm and respiratory distress.

Central Nervous System: Reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation of time and place, short-term memory loss, emotional lability with slightly clouded sensorium, decreased performance on neuropsychometrics.

Gastrointestinal: Mesenteric arterial thrombosis, ischemic colitis.

Other: Reversible alopecia, Peyronie's disease, erythematous rash, Raynaud's phenomenon.

Miscellaneous: The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with TENORMIN during investigational use and foreign marketing experience. Furthermore, a number of patients who had previously demonstrated established practolol reactions were transferred to TENORMIN therapy with subsequent resolution or quiescence of the reaction.

OVERDOSAGE: To date, there is no known case of acute overdosage, and no specific information on emergency treatment of overdosage is available. The most common effects expected with overdosage of a beta-adrenergic blocking agent are bradycardia, congestive heart failure, hypotension, bronchospasm, and hypoglycemia.

In the case of overdosage, treatment with TENORMIN should be stopped and the patient carefully observed. TENORMIN can be removed from the general circulation by hemodialysis. In addition to gastric lavage, the following therapeutic measures are suggested if warranted:

Bradycardia: Atropine or another anticholinergic drug.

Heart Block (Second or Third Degree): Isoproterenol or transvenous cardiac pacemaker.

Congestive Heart Failure: Conventional therapy.

Hypotension (Depending on Associated Factors): Epinephrine rather than isoproterenol or norepinephrine may be useful in addition to atropine and digitalis.

Bronchospasm: Aminophylline, isoproterenol, or atropine.

Hypoglycemia: Intravenous glucose.

DOSAGE AND ADMINISTRATION: The initial dose of TENORMIN is 50 mg given as one tablet a day either alone or added to diuretic therapy. The full effect of this dose will usually be seen within one to two weeks. If an optimal response is not achieved, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Increasing the dosage beyond 100 mg a day is unlikely to produce any further benefit.

TENORMIN may be used alone or concomitantly with other antihypertensive agents including thiazide-type diuretics, hydralazine, prazosin, and alpha-methyldopa.

Since TENORMIN is excreted via the kidneys, dosage should be adjusted in cases of severe impairment of renal function. No significant accumulation of TENORMIN occurs until creatinine clearance falls below 35 ml/min/1.73 m² (normal range is 100-150 ml/min/1.73 m²); therefore, the following maximum dosages are recommended for patients with renal impairment:

Creatinine Clearance (ml/min/1.73 m²)	Atenolol Elimination Half-life (hrs)	Maximum Dosage
15-35	16-27	50 mg daily
<15	>27	50 mg every other day

Patients on hemodialysis should be given 50 mg after each dialysis; this should be done under hospital supervision as marked falls in blood pressure can occur.

HOW SUPPLIED: Tablets of 50 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 105 embossed on the other side are supplied in monthly calendar packages of 28 tablets, bottles of 100 tablets, and unit-dose packages of 100 tablets. Tablets of 100 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 101 embossed on the other side are supplied in bottles of 100 tablets and unit-dose packages of 100 tablets.

Protect from heat, light, and moisture. Store unit-dose and calendar packages at controlled room temperature.

CONTENTS

MISCELLANEOUS TOPICS

359 Physical Conditioning and Left Ventricular Performance in the Elderly: Assessment by Radionuclide Angiocardiography

DOUGLAS D. SCHOCKEN, JAMES A. BLUMENTHAL, STEVEN PORT, PAULA HINDLE, and R. EDWARD COLEMAN

To assess the effects of physical training on left ventricular (LV) performance in the elderly, a group of 24 norma elderly persons (mean age 72 years) screened for cardiovascular disease underwent examination of LV functio by rest and exercise radionuclide angiocardiography (RNA) both before and after a 12-week physical condi tioning program. After training, the subjects' functional capacity and double product at a matched submaxima work load had improved significantly. RNA disclosed increased exercise LV end-diastolic volume index and car diac index after the conditioning program. However, both the exercise-induced decrease in LV ejection fractio and concomitant increase in LV end-systolic volume noted before training persisted. These findings suggest tha deconditioning is not a significant contributor to the decline in LV contractile performance seen in the elderly.

365 Abnormal Thallium-201 Scans in Patients With Chest Pain and Angiographically Normal Coronary Arteries

BRUCE C. BERGER, RICHARD ABRAMOWITZ, CHAN H. PARK, ANIL G. DESAI, MARK T. MADSEN, EDWARD K. CHUNG, and ALBERT N. BREST

We reviewed the exercise thallium-201 (T1-201) scans and clinical data in 41 patients with chest pain and nor mal coronary arteries to identify clinical factors associated with false-positive studies. The studies were per formed before angiography and often precipitated referral. Of the 41 patients, 11 (27%) had abnormal exercis T1-201 scans. No clinical factor was significantly associated with a false-positive T1-201 study. Of the 11 pa tients with abnormal scans, 9 had ≥ 1 cardiac abnormality, including mitral valve prolapse, conduction abnor malities and abnormal left ventricular diastolic pressure. Thus, (1) when results of exercise T1-201 imaging ar used to refer patients for angiography, false-positive T1-201 studies are common; (2) clinical factors do not pre dict false-positive T1-201 studies; and (3) patients with chest pain, normal coronary arteries, and abnormal T1 201 scans frequently have other cardiac abnormalities.

371 Natural History of Platelet Deposition on Dacron Aortic Bifurcation Grafts in the First Year After Implantation

JOHN R. STRATTON, BRIAN L. THIELE, and JAMES L. RITCHIE

Indium-111 platelet imaging was performed on 8 men 1 to 2 weeks after Dacron® arterial graft implantation anc in 5 of these patients, at a mean of 31 and 55 weeks. Serial imaging was performed 24 to 96 hours after platele labeling. Quantitative analysis was performed using a graft/blood ratio that compared background-correcte platelet activity in the graft region to whole blood platelet activity. Additionally, blinded qualitative visual analysi of the images compared graft activity with the activity in adjacent native arteries. The mean of all graft/blood ra tios (24, 48, 72, and 96 hours) progressively decreased from 4.4 ± 2.1 (± 1 standard deviation) at 1 to 2 week to 3.0 ± 1.8 at 31 weeks ($p = 0.002$). There was no further decrease at 55 weeks (2.8 ± 2.0). For comparisor 12 normal subjects without grafts had a mean ratio of 1.8 ± 0.7. Visual analysis detected platelet deposition i 7 of 8 grafts at 1 to 2 weeks, 4 of 5 at 31 weeks, and 4 of 5 at 55 weeks. Deposition decreased qualitatively i 2 of 5 patients at late study. It is concluded that there is consistent, early platelet deposition on Dacron grafts i humans. Although deposition decreases over 31 weeks, it remains readily detectable in most patients at 1 yea These findings suggest absent or incomplete endothelialization of the graft flow surface in man in the first yea after implantation.

METHODS

375 Systematic Analysis of Contrast Echocardiograms

RICHARD S. MELTZER, ZVI VERED, JOS ROELANDT, and HENRY N. NEUFELD

Contrast echocardiography was first described in 1968, and many articles since then have described clinical an experimental uses for the technique. It is performed at least occasionally in most echocardiography laborat ries. However, most physicians use this technique merely to obtain a "yes-no" answer with respect to the pres ence of a shunt or, more rarely, structure identification. Much more information is potentially available tha merely yes or no. This report reviews some of the different types of information available from contrast echoca diographic records (timing of contrast appearance within the cardiac cycle, relative timing of appearance in di ferent cardiac structures, relative intensity of contrast opacification, cyclic changes in contrast opacificatio negative contrast effect, slope of contrast trajectories on M-mode contrast echocardiography and clearanc times).

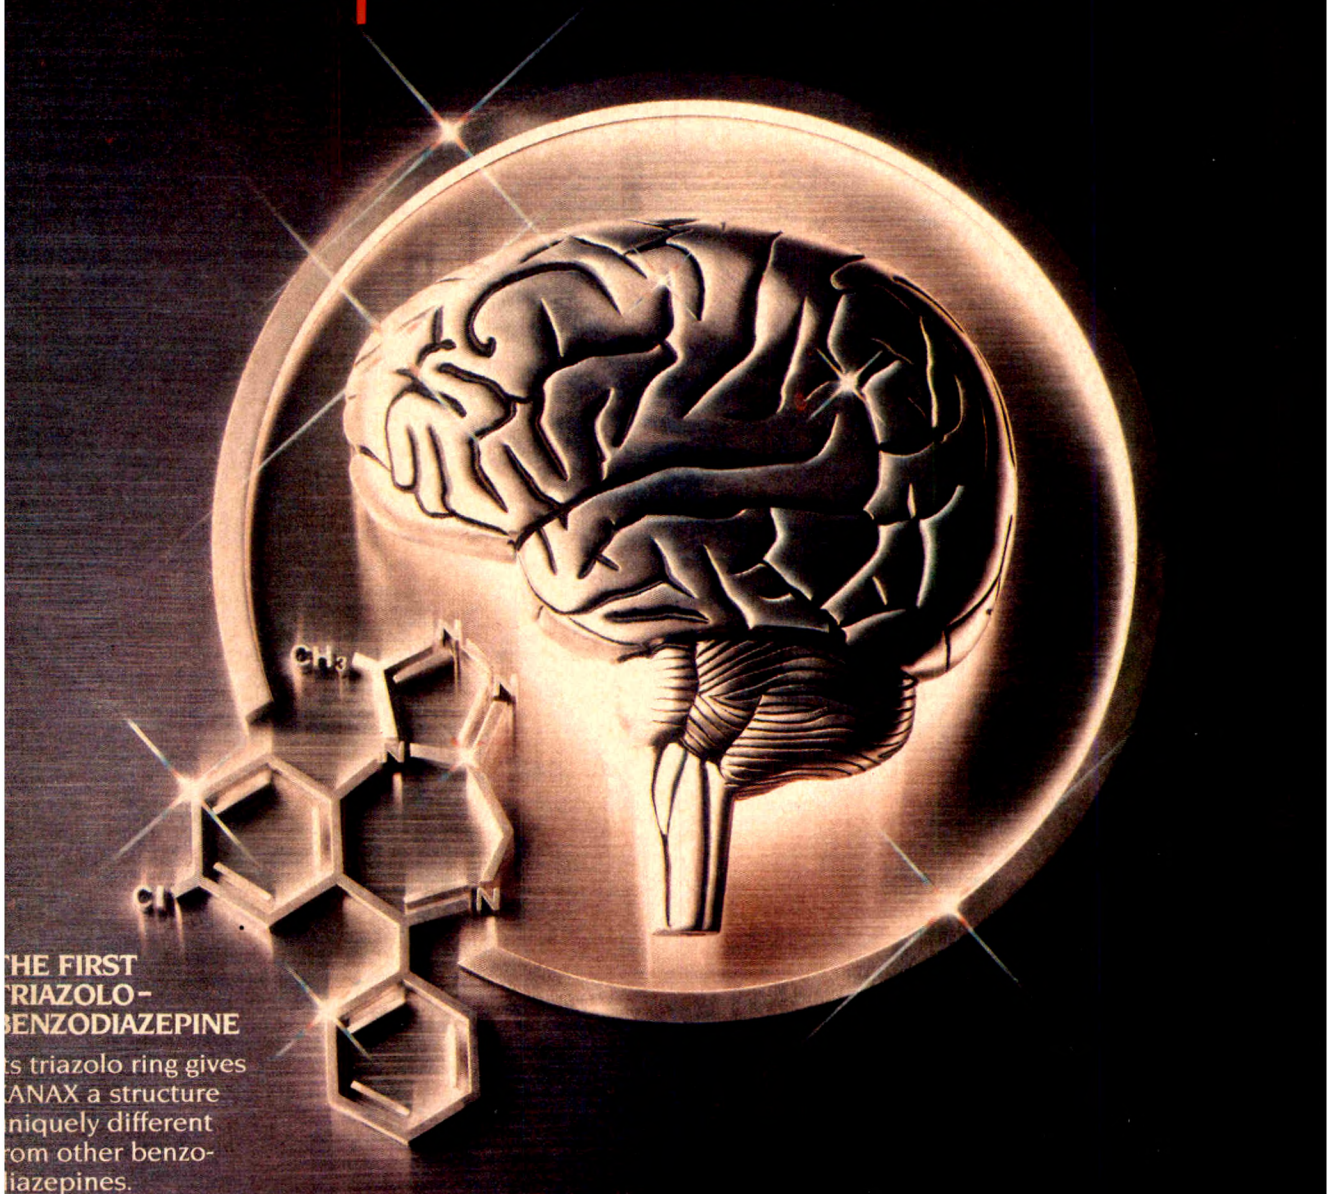
Xanax® 0.5 mg Tablets

alprazolam C-IV



THE FIRST TRIAZOLO-BENZODIAZEPINE

Its triazolo ring gives XANAX a structure uniquely different from other benzodiazepines.

THE FIRST OF A UNIQUE CLASS

Upjohn

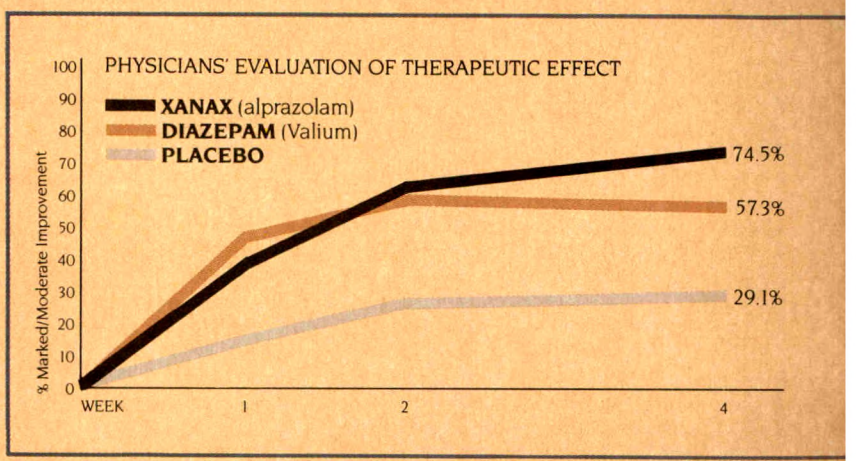
© 1982 The Upjohn Company

FOR CLINICAL ANXIETY

EFFICACY EQUAL TO DIAZEPAM WITH LESS DROWSINESS

In double-blind, placebo-controlled clinical trials in 976 patients with moderate to severe clinical anxiety, therapy with XANAX was compared to diazepam (Valium).*

Patients treated with XANAX *had a significantly lower incidence of drowsiness when compared directly to diazepam* therapy (Valium) in *a 976-patient,* placebo-controlled, multicenter study.*

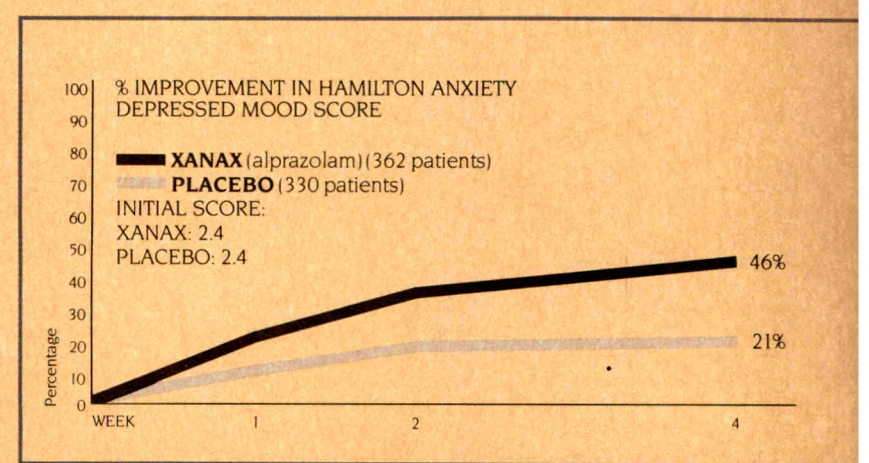


AND CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

EFFECTIVE IN CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

Patients with clinical anxiety may complain of having feelings of depression, such as sadness, blueness, or loneliness.

Depressed mood is one of 14 items on the Hamilton Anxiety Rating Scale. Special analysis of 692 anxious patients with a significant depressed mood item score showed that treatment with XANAX was significantly better than placebo in decreasing depressed mood score.



SIMPLE DOSAGE: XANAX 0.25–0.5 mg T.I.D.

The usual starting dose of XANAX is 0.25 to 0.5 mg, three times daily.

Please see next page for brief summary of prescribing information.

Xanax® 0.5 mg Tablets

alprazolam Ⓒ℞

XANAX® Tablets ℞
(alprazolam)

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation (see Drug Interaction section). Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage (see Dosage and Administration). Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central Nervous System: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other Side Effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analyses are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. After prolonged therapy, dosage should be tapered. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION. BS-1

CLASSIFIED

ASSISTANT/ASSOCIATE PROFESSOR OF MEDICINE

Cardiology Unit, University of Vermont

Full-time position in Department of Medicine. Major responsibilities include Director of Coronary Care unit, teaching of acute cardiac care, special skills required in either cardiac catheterization, cardiac electrophysiology or nuclear cardiology and an ability to develop fundable independent research programs is essential. Applicants must be Board certified or eligible in Cardiology and possess a minimum of 3 years training in Cardiology. Send inquiries with CV by October 1 to Dr. Arthur M. Levy, Cardiology Unit, Medical Center Hospital of Vermont, Burlington, VT 05401. The University of Vermont is an Affirmative Action Employer. Women and minorities are encouraged to apply.

CARDIOLOGIST B.C. to join two busy cardiologists in suburban office/hospital private practice in large upper midwest city. Good salary. Early full partnership. All invasive/non-invasive skills preferred. Reply to Box 275, The American Journal of Cardiology, 875 Third Ave., New York, N.Y. 10022.

Cardiologist — For private referral consultative practice. Based on Cardiac Catheterization, Cardiac consultation and non invasive Cardiac diagnostic testing. Major Medical Center with active cardiac surgical program performing daily Cardiac surgery. Large referral area. Located in Sunbelt. Prefer recently completed fellowship. Send C.V. and letter outlining practice interests to Box 270, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

ACADEMIC CARDIOLOGIST—Full time faculty position at Associate or Assistant Professor level available in Division with expanding research programs in electrophysiology, hemodynamics, hypertension, imaging and metabolism. Candidates must be fully-trained cardiologists with potential for independent basic or clinical investigation. Reply to Jay M. Sullivan, M.D., Chief, Division of Cardiovascular Diseases, University of Tennessee Center for the Health Sciences, 951 Court Avenue, Memphis, TN 38163. An equal opportunity, affirmative action employer.

381 Left Atrial Abnormality As an Electrocardiographic Criterion for the Diagnosis of Left Ventricular Hypertrophy in the Presence of Right Bundle Branch Block

MARVIN L. MURPHY, NIHAL THENABADU, NEIL de SOYZA, JAMES E. DOHERTY, and BONNIE J. BAKER

Left atrial (LA) abnormality determined from precordial lead V_1 was assessed by 2 observers as a criterion of left ventricular (LV) hypertrophy in the presence of right bundle branch block (BBB) in 23 patients. The presence of LV hypertrophy was confirmed from a postmortem cardiac partition technique and defined at 2 levels of confidence: probable and definite hypertrophy. The 2 observers differentiated between the hypertrophied and normal-sized ventricle in most instances in the presence of right BBB by using LA abnormality as an electrocardiographic criterion. Observer performance of recognition of LA abnormality in this study was satisfactory, with 91% agreement between observers. Our results are comparable and, in some instances, superior to other criteria commonly recommended to diagnose LV hypertrophy on the electrocardiogram without right BBB.

384 Automatic Computer Processing of Digital 2-Dimensional Echocardiograms

ANDREW J. BUDA, EDWARD J. DELP, CHARLES R. MEYER, JANICE M. JENKINS, DAVID N. SMITH, FRED L. BOOKSTEIN, and BERTRAM PITT

The development of automatic computerized methods should improve the ability to extract quantitative data from 2-dimensional echocardiographic studies and improve the reliability of these data. A method of direct digital acquisition that improves signal-to-noise ratio, and thus improves endocardial and epicardial border definition has been developed. Using edge detection algorithms, it has been possible to automatically define anatomically appropriate endocardial and epicardial borders. Subsequent left ventricular regional and global analysis can be performed quantitatively frame by frame. These technologic improvements in 2-dimensional echocardiographic data acquisition and processing should facilitate quantitative studies in the analysis of left ventricular function.

EXPERIMENTAL STUDIES

390 Early Degradation of Collagen After Acute Myocardial Infarction in the Rat

RICHARD O. CANNON, III, JAGDISH W. BUTANY, BRUCE M. McMANUS, EDITH SPEIR, ALAN B. KRAVITZ, ROBERTO BOLLI, and VICTOR J. FERRANS

Collagen, which forms a structural fibroskeleton in healthy myocardium, was measured in infarct tissue from control rats at 24 hours after coronary artery ligation, and rats made leukopenic by prior whole-body irradiation (white blood cell count $<300/mm^3$). Control rats had a 25% decrease in myocardial hydroxyproline content compared with unoperated rats, associated histologically with an influx of inflammatory cells at the infarct margins. There was no significant collagen degradation in leukopenic rats. Electron microscopic studies revealed greater preservation of collagen in the 24-hour-old infarcts of leukopenic rats than in those of controls. These results suggest that there is early collagen degradation after myocardial infarction, which is mediated by inflammatory cells and may be of pathogenetic importance in the development of cardiac rupture and aneurysm formation.

396 Assessment of Quantitative Methods for 2-Dimensional Echocardiography

HORACE L. WYATT, ROBERTO V. HAENDCHEN, SAMUEL MEERBAUM, and ELIOT CORDAY

Several 2-dimensional echocardiographic (2-DE) methods were tested in vitro for accuracy of linear and cross-sectional measurements and in vivo for left ventricular (LV) volume reconstruction. With echocardiographic low and high gains and with precise in vitro calibrations, we studied myocardial slice thickness measured by leading-trailing, trailing-leading, and leading-leading methods. Regression analysis of echocardiographic versus direct measurements yielded excellent correlations for all 3 methods, with an interobserver variability of <3%. Accuracy of measurement was satisfactory only for the leading-leading method. Thin myocardial slices were applied to cylinders and fixed in formalin to produce precise cavity areas. Regression analysis of echocardiographic versus actual cavity area gave high correlations, and low interobserver variability for both inner and leading edge methods, but leading edge was most accurate. Although in vivo 2-DE echocardiography in dogs underestimated angiographic volumes, generally good correlations were obtained. The leading edge method showed the least underestimation. Thus, for 2-DE, the leading edge method is most accurate for linear and cross-sectional measurements of myocardium and for application to LV volumes.

HYLOREL: A New Peripheral Sympathetic Inhibitor

HYLOREL controls blood pressure via peripheral, not CNS, action... allowing relaxation of the arterioles. Some CNS effects have been reported in patients treated with antihypertensive regimens that included HYLOREL. With a diuretic, HYLOREL is useful in the Step-2 treatment of hypertension.

HYLOREL is a well-tolerated alternative to beta blockers, prazosin, and centrally acting antihypertensives, when a diuretic alone is not enough.

As Effective as Aldomet®*[1]

HYLOREL, in controlled clinical studies, provided blood pressure control comparable to Aldomet, with less drowsiness, depression, and impotence. Patients treated with Aldomet had less diarrhea and fewer orthostatic effects than did those treated with HYLOREL Tablets (guanadrel sulfate).[1]

Orthostatic hypotension, diarrhea, and ejaculation disturbances may occur in patients but seldom have been a cause for discontinuing HYLOREL therapy (see Table 1).

Table 1.
Percent of Patients Discontinuing Therapy

	HYLOREL	Methyldopa	Guanethidine
orthostatic faintness	0.6	0.7	6.0*
syncope	0.4	0.3	2.0
other faintness	1.2	0.0	0.0
increased bowel movements	0.8	0.7	1.4
drowsiness	0.0	1.9*	0.0
fatigue	0.2	2.6*	0.0
ejaculation disturbances	0.4	0.0	0.0
Number of patients analyzed	(481)	(271)	(222)

*Significantly greater than HYLOREL ($p<0.003$).

A Well-tolerated and Useful Choice for Step-2 Treatment of Hypertension

HYLOREL, with a diuretic, is easy to use and economical... for the Step-2 treatment of hypertension.

HYLOREL has not caused a significant change in cardiac output nor adverse effects on liver function.

HYLOREL should not be used in patients with pheochromocytoma nor concurrently with monoamine oxidase inhibitors. HYLOREL should not be given to patients with frank congestive heart failure.

HYLOREL is not contraindicated in patients with ischemic heart disease or peripheral vascular disease.

Two Doses a Day for Most Patients With Hypertension

HYLOREL is prompt acting and rapidly cleared. The dosage can be conveniently titrated. Two doses per day adequately control blood pressure for 24 hours and are associated with minimal morning orthostatic hypotension. Dosage may be adjusted weekly or monthly to fit the patient's needs.

HYLOREL is a Step-2 therapy and should be added to a diuretic regimen for optimal blood pressure control. HYLOREL should be given in divided doses... the usual starting dose is 10 mg per day. The dosage range for most patients is 20 to 70 mg per day.

New for hypertension from Pennwalt

Hylorel® 10 & 25 mg Tablets (GUANADREL SULFATE)

Please refer to the brief summary, including Warnings and Adverse Reactions, on the following page.

Hylorel® 10 & 25 mg Tablets
(GUANADREL SULFATE)

Before prescribing see complete prescribing information; a brief summary follows.

DESCRIPTION: HYLOREL Tablets contain guanadrel sulfate—an antihypertensive agent belonging to the class of adrenergic neuron inhibitors.

CLINICAL PHARMACOLOGY: Guanadrel sulfate is an orally effective antihypertensive agent that lowers both systolic and diastolic arterial blood pressures. Guanadrel sulfate inhibits sympathetic vasoconstriction by inhibiting norepinephrine release from neuronal storage sites and also causes depletion of norepinephrine from nerve endings. This results in relaxation of vascular smooth muscle. No significant change in cardiac output accompanies the blood pressure decline in normal individuals.

INDICATIONS AND USAGE: HYLOREL is indicated for the treatment of hypertension in patients not responding adequately to a thiazide-type diuretic. HYLOREL is Step-2 therapy and should be added to a diuretic regimen for optimum blood pressure control.

CONTRAINDICATIONS: Known or suspected pheochromocytoma; concurrently or within one week of the use of monoamine oxidase inhibitors; patients hypersensitive to the drug; patients with frank congestive heart failure.

WARNINGS: Orthostatic Hypotension and its consequences (dizziness and weakness) are frequent in people treated with HYLOREL. Rarely, fainting upon standing or exercise is seen. Patients with known regional vascular disease (cerebral, coronary) are at particular risk from marked orthostatic hypotension, and HYLOREL should be avoided in them unless drugs with lesser degrees of orthostatic hypotension are ineffective or unacceptable.
Surgery—HYLOREL should be discontinued 48–72 hours before elective surgery to reduce the possibility of vascular collapse during anesthesia. If emergency surgery is required, the anesthesiologist should be made aware that the patient has been taking HYLOREL, and that preanesthetic and anesthetic agents should be administered cautiously in reduced dosage. If vasopressors are needed, they must be used cautiously, as guanadrel can enhance the pressor response to such agents and increase their arrhythmogenicity.
Drug Interactions—Tricyclic antidepressants and indirect-acting sympathomimetics can reverse the effects of neuronal blocking agents. IN VIEW OF THE PRESENCE OF SYMPATHOMIMETIC AMINES IN MANY NON-PRESCRIPTION DRUGS FOR THE TREATMENT OF COLDS, ALLERGY, OR ASTHMA, PATIENTS GIVEN GUANADREL SHOULD BE SPECIFICALLY WARNED NOT TO USE SUCH PREPARATIONS WITHOUT THEIR PHYSICIAN'S ADVICE. Drugs that affect the adrenergic response by the same mechanisms as guanadrel sulfate or by other mechanisms would be expected to potentiate the effects of HYLOREL causing excessive postural hypotension and bradycardia. These include alpha or beta adrenergic blocking agents and reserpine. There is no clinical experience with such combinations.
Asthmatic patients with bronchial asthma: need special attention as their condition may be aggravated by catecholamine depletion and sympathomimetic amines may interfere with the hypotensive effect of guanadrel.

PRECAUTIONS: General—Salt and water retention may occur. In clinical studies, major problems did not arise because of concomitant diuretic use. Patients with heart failure and patients with renal failure have not been studied on HYLOREL. HYLOREL should be used cautiously in patients with a history of peptic ulcer.
Carcinogenesis—No evidence of carcinogenic potential appeared in animal studies.
Mutagenesis—Salmonella testing showed no evidence of activity.
Pregnancy Category B
Impairment of fertility and teratogenic effects—Reproduction studies in rats and rabbits have revealed no evidence of impaired fertility or harm to the fetus due to HYLOREL. There are no adequate and well-controlled studies in pregnant women. HYLOREL should be used in pregnant women only when the potential benefit outweighs the potential risk to mother and infant.
Nursing mothers—It is not known whether or not guanadrel sulfate is excreted in human milk.
Pediatric Use—Safety and effectiveness of guanadrel in children have not been established.

ADVERSE REACTIONS: The adverse reaction data in this section are derived principally from comparative long-term studies with methyldopa and guanethidine. Side effects were assessed through the use of periodic questionnaires, a method that tends to give high adverse reaction rates. Reasons for discontinuation of therapy are shown in the following table.

PERCENT OF PATIENTS WHO DISCONTINUED THERAPY

	Guanadrel	Methyldopa	Guanethidine
Orthostatic faintness	0.6	0.7	6.0
Syncope	0.4	0.3	2.0
Other faintness	1.2	0.0	0.0
Increased bowel movements	0.8	0.7	1.4
Drowsiness	0.0	1.9	0.0
Fatigue	0.2	2.6	0.0
Ejaculation disturbances	0.4	0.0	0.0

The following percentages represent the number of patients who reported an event at least once over the treatment periods (6 months to 3 years). For such long-term studies, these rates for side effects, often found in untreated people as well as in association with adrenergic neuron blocking agents, tend to be high and accumulate with time. The rates for methyldopa and guanethidine should aid in interpretation of this information. It can be seen that serious consequences of the orthostatic effect of guanadrel, such as syncope were very uncommon.

1544 guanadrel, 330 guanethidine and 743 methyldopa patients were evaluated in comparison studies. The observed incidence rates of major drug-related side effects for guanadrel, guanethidine and methyldopa respectively are as follows: Orthostatic faintness: 49%, 48%, 41%; other faintness: 47%, 45%, 46%; increased bowel movements: 31%, 36%, 28%; ejaculation disturbances:18%, 22%, 21%; impotence: 5.1%, 7.2%, 12.2%; syncope: 0.4%, 2%, 0.3%; urine retention: 0.2%, 0%, 0%. Apart from these adverse effects, many others were reported. Relationship to therapy is less clear, although some (such as peripheral edema with all three drugs, depression with methyldopa) are in part drug related. All adverse effects reported in at least 1% of guanadrel patients are listed in the full prescribing information. (This is a brief summary.)

DOSAGE AND ADMINISTRATION: As with other sympathetic suppressant drugs, the dose response to HYLOREL varies widely and must be adjusted for each patient until the therapeutic goal is achieved. With long-term therapy, some tolerance may occur and the dosage may have to be increased.
Because HYLOREL has a substantial orthostatic effect, monitoring both supine and standing pressure is essential, especially while dosage is being adjusted.
HYLOREL should be administered in divided doses. The usual starting dosage for treating hypertension is 10 mg per day, which can be given as 5 mg b.i.d. by breaking the 10 mg tablet. Because the half-life is approximately ten hours, the dosage should be adjusted weekly or monthly until blood pressure is controlled. Most patients will require daily dosage of the range of 20 to 75 mg usually in twice daily doses. For larger doses 3 or 4 times daily dosing may be needed.

COMBINATION THERAPY: HYLOREL has not been studied in combination with antihypertensive drugs other than thiazide diuretics.

HOW SUPPLIED: HYLOREL Tablets (guanadrel sulfate) are available as follows:
10 mg, scored elliptical tablets (light orange)
Bottles of 100 NDC 0018-0787-71
25 mg, scored elliptical tablets (white)
Bottles of 100 NDC 0018-0788-71

Caution: Federal law prohibits dispensing without a prescription.

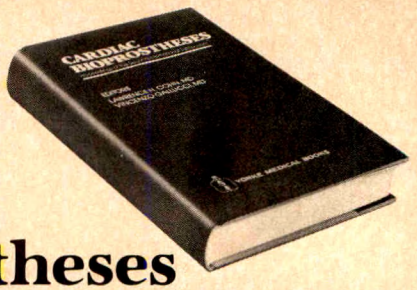
The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.



Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

The pacers are now.

Cordis Sequicor® II.

The first long-life (10-year*) DDD pacer, with telemetry and independently programmable atrial refractory periods to prevent pacer-mediated tachycardia.

Cordis Multicor® II.

A fully programmable single-chamber pacer. You can even program from unipolar to bipolar and back again, so you can solve myopotential inhibitions without creating undersensing problems.

*Predicted theoretical service life of 10 years based on 100% dual-chamber demand (DDD) pacing at 70 ppm and delivering 0.6 ms/6 mA pulse into a 510-ohm load.

The way you manage them isn't.

The Multicor II and Sequicor II pacers share the portable hand-held Cordis Programmer III and the same simple programming sequences for all parameters and values.

And both pacers give your patients the security of redundant circuits, our Patient Safety System, which continues pacing even in the unlikely event of random component malfunction.

Please call the toll-free number below for more information on the Multicor II and Sequicor II pacers from Cordis.

When you know how to manage one, you know how to manage the other.

cordis®

Cordis Corporation, P.O. Box 025700, Miami, Florida 33102-5700, U.S.A.

Important Information

Cordis Implantable Pacers and Programmers

Indications and Contraindications

The medical literature describes currently accepted indications and contraindications for the various pacing/sensing modes. However, the physician's clinical experience and judgment must ultimately determine the pacing mode best suited to the patient's needs.

When spontaneous beats are expected, a sensing mode (inhibited or triggered) is indicated. *Asynchronous pacing is contraindicated for long-term pacing when inherent activity is present or likely to be present in the chamber being paced.*

Pacing of the ventricles (VVI or VVT) is indicated for controlling slow heart rate in patients with A-V block and/or sick sinus syndrome. Atrial pacing (AAI or AAT) is indicated for controlling heart rate, increasing cardiac output, and suppressing premature ventricular contractions (PVCs) in patients with intact A-V conduction and sick sinus syndrome. *Atrial pacing is contraindicated when A-V conduction disturbances are present.*

Atrial-synchronized ventricular pacing (VVD or VAT) and dual-chamber pacing (DVI or DDD) are indicated for patients who would benefit from restoration of atrial contribution to cardiac output and the control of heart rate. Atrial-synchronized ventricular pacing is indicated for patients with permanent heart block and normal atrial rhythm. Dual-chamber pacing is indicated for A-V conduction disturbances with sinus node dysfunction (sinus bradycardia with A-V block, bradytachy syndrome). *Atrial-synchronized ventricular pacing and automatic dual-chamber demand pacing modes are contraindicated in the presence of persistent atrial flutter or atrial fibrillation.* The VVI mode is recommended for these conditions.

Cordis programmers are designed to noninvasively control the operating parameters and modes of Cordis programmable cardiac pacers.

Precautions

Cordis implantable pacers may respond to programmers of other manufacturers. Because of the unknown nature of such response, use only the Cordis Model 255A Programmer III for reprogramming.

Use pacers on a first-in, first-out basis prior to the "Use before" date on the package.

Warnings

None

Adverse Effects

A number of complications related to pacer therapy have been reported in the medical literature. The complications listed below may occur at any time after implantation.

Pacer – battery depletion, electromagnetic interference, component malfunction, decreased sensitivity.

Lead – unsatisfactory electrode position, fracture, displacement, perforation of heart wall, faulty connection with pacer, migration through body tissue.

Patient – reaction, infection/erosion, increase in stimulation threshold, embolism, thrombosis.

Caution: Federal (U.S.A.) law restricts these devices to sale by or on the order of a physician.

Prior to use, refer to the *Instructions for Use* for more information.

NITRODISC™

(NITROGLYCERIN)

5 mg/24 hr
10 mg/24 hr discs

DESCRIPTION: Nitrodisc incorporates a patented Microseal Drug Delivery™ system consisting of a solid, nitroglycerin-impregnated polymer bonded to a flexible, non-sensitizing adhesive bandage. It is designed to be applied topically. Nitrodisc provides constant and controlled drug delivery over a uniform skin surface area for 24 hours.

Nitrodisc is available in two strengths which release either 5 mg or 10 mg of nitroglycerin during a 24-hour period. The 5 mg/24 hr system contains 16 mg nitroglycerin over an 8 cm^2 releasing surface. The 10 mg/24 hr system contains 32 mg nitroglycerin over a 16 cm^2 releasing surface.

INDICATIONS AND USAGE: Nitrodisc is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Nitrodisc (nitroglycerin) is contraindicated in patients known to be intolerant of organic nitrate drugs, and in patients with marked anemia, increased intraocular pressure, or increased intracranial pressure.

WARNINGS: In patients with acute myocardial infarction or congestive heart failure, Nitrodisc should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of patients with angina, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent potential withdrawal reactions, which are characteristic of all vasodilators in the nitrate class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness, or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Nitrodisc is not intended for immediate relief of anginal attacks. For this purpose, occasional use of sublingual preparations may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Nitrodisc therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, Nitrodisc (nitroglycerin) dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION: Nitrodisc should be applied once each day. To use Nitrodisc, follow the instructions on the package. Nitrodisc should be applied to an intact skin site free of hair and not subject to excessive movement. It should not be applied to the distal parts of the extremities. A suitable area should be shaved free of hair, if necessary. The application site should be changed slightly each time to avoid undue skin irritation. A new Nitrodisc should be applied if the product loosens.

The optimal dosage regimen should be selected based upon the clinical response, the side effects, and the effects of therapy upon blood pressure and heart rate. It is recommended that therapy be initiated with the smaller Nitrodisc, and that the larger Nitrodisc be utilized when a greater response is desired. In the event that higher doses are necessary, multiple pads may be applied.

The best images and a unique technology...

The new PASS™ echocardiography system from General Electric expands the advantages of phased array ultrasound...and delivers a difference in M-mode and 2D images beyond your expectations.

More accurate clinical information, faster

Only GE applies baseband signal processing to phased array echocardiography and couples it with superior transducer design. Your clinical studies reap the benefits of this exclusive combination.

Specifically, baseband processing, with its greater signal timing accuracy, significantly improves image resolution and penetration. And baseband processing eliminates artifacts and other types of electronic noise. A continuous focusing ability provides a focused view of the heart from the near field to the deepest penetration; an important improvement over the zone focusing of other systems. As a result, you can image structures as fine as 1 mm; see better edge definition; and can differentiate soft tissue more precisely. Also, advanced phased array display capability permits time-efficient simultaneous viewing of M-mode and 2D images. Two M-mode images or two 2D images allow accurate quantification and diagnostic flexibility.

Image a wider range of patients with more transducer options

From premature neonate to obese adult, the PASS system widens the range of scannable patients. For neonatal and pediatric studies, the PASS system offers the first clinically proven 5 MHz phased array image without near field noise. Average size adults can be imaged at 3.3 MHz for optimal resolution. Obese adults can be imaged at 2.5 MHz for maximum penetration. And because PASS is a phased array system, its small, lightweight transducers offer better acoustic access compared to mechanical sector systems.

More options for future capability

Best of all, you can build on today's PASS system capability for tomorrow's imaging requirements. Because upgradeability is designed-in, you'll soon be able to add doppler; plus other technological advances as they are developed. In addition, self-diagnostic features facilitate servicing and help keep the system on the job.

See the difference the PASS system can make in your clinical studies. Contact your GE representative.

...clinical studies you can trust.

We bring good things to life.

CORONARY HEART DISEASE

Coronary Reperfusion and Bezold-Jarisch Reflex (Bradycardia and Hypotension)

PAOLO ESENTE, MD, ALESSANDRO GIAMBARTOLOMEI, MD, GOFFREDO G. GENSINI, MD, and CARLOS DATOR, MD

This study reports the occurrence of bradycardia and hypotension (Bezold-Jarisch reflex) induced by myocardial reperfusion. Among 92 patients undergoing interventional catheterization for intracoronary thrombolysis in an early phase of acute myocardial infarction, left anterior descending, right coronary, and left circumflex (LC) arteries were identified as the "infarct vessel" in 44, 41, and 7 cases, respectively. The Bezold-Jarisch reflex occurred in 15 of 23 patients (65%) after right coronary recanalization and in 1 of 34 patients after left anterior descending recanalization. The reflex also was observed in 4 (22%) of 18 patients with nonoccluded or nonrecanalized right coronary arteries. The average time from onset of symptoms to righ recanalization was significantly shorter ($p < 0.01$) among patients in whom the reflex did not develop Atropine, postural changes, or temporary pacing, o all 3, were generally sufficient to control symptoms The findings of this study are substantially paralle to those reported by others and confirm that reper fusion of the inferoposterior myocardium is capable of stimulating a cardioinhibitory reflex. Follow-up data available in 15 patients with occluded and re canalized right coronary arteries indicate that the occurrence of the Bezold-Jarisch reflex after re perfusion is not a reliable predictor of myocardia salvage.

The Bezold-Jarisch reflex, an inhibitory reflex characterized by bradycardia and hypotension, is induced by stimulation of receptors situated in the left ventricle.[1,2] These receptors signal in nonmyelinated vagal afferent fibers and respond to chemical, mechanical, or metabolic stimuli.[3–5] In the cat, increased discharge from left ventricular receptors was noted after coronary occlusion as well as reperfusion.[5]

Ischemia-activated vagal afferent receptors are located primarily in the inferoposterior wall of the canine heart.[6] The exact location of similar receptors in man has not been determined experimentally. However, th high incidence of bradycardia-hypotension syndrom observed during the early phase of inferior myocardia infarction[7] strongly suggests that in the human heart such receptors are situated in the inferoposterior lef ventricular wall. This study reports the occurrence o the Bezold-Jarisch reflex induced by myocardial re perfusion in man.

Methods

From May 1981 through December 1982, 92 patients un derwent cardiac catheterization, coronary angiography, an intracoronary streptokinase infusion during the early hour of an evolving acute myocardial infarction. The procedur started <6 hours from the onset of symptoms in 84 patients At the inception of catheterization, all patients had unequiv ocal electrocardiographic evidence of acute injury and all bu 1 had chest pain. Cardiogenic shock was present in 4 pa tients.

TABLE I Settings of the Bezold-Jarisch Reflex

	Infarct Vessel		
	LAD (44 pts)	RCA (41 pts)	Cx (7 pts)
Recanalized	34	23	4
Bezold-Jarisch reflex	1(3%)	15(65%)	0
Not recanalized	6	9	3
Bezold-Jarisch reflex	0	2(22%)	0
Not occluded	4	9	0
Bezold-Jarisch reflex	0	2(22%)	. . .

Cx = left circumflex artery; LAD = left anterior descending artery; RCA = right coronary artery.

All patients were premedicated with hydrocortisone, diphenhydramine, and morphine sulfate as required. After a bolus of 50 to 100 mg, lidocaine was infused at a rate of 2 to 4 mg/min. Nonhypotensive patients received nitroglycerin at a rate of 15 to 120 μg/min. The Sones technique was used in all cases. Intracoronary nitroglycerin, 0.4 mg bolus, was injected into the "infarct" vessel (that is, the obstructed or occluded branch supplying the infarcted area) followed by a streptokinase bolus of 10,000 U and constant streptokinase infusion at 4,000 U/min through a pressurized drip. Control visualization of the "infarct" vessel was obtained at 5- to 15-minute intervals or when rhythm changes were noted. Leads III and V_5 were monitored in anterior infarctions, leads I and III in inferior infarctions.

Results

Arteriographic findings: Left anterior descending (LAD), right coronary, and left circumflex (LC) coronary arteries were identified as the "infarct" vessel in 44, 41, and 7 cases, respectively. The "infarct" vessel was not occluded in 13 patients (4 LAD and 9 right coronary arteries).

Intracoronary thrombolysis: Recanalization of occluded coronary arteries was achieved in 34 of 40 LAD, in 23 of 32 right coronary, and in 4 of 7 LC arteries. The average recanalization time from the onset of symptoms was 215 minutes.

Bezold-Jarisch reflex: Hypotension and bradycardia (either sinus or secondary to atrioventricular block) occurred in 20 patients (22%). The settings in which the Bezold-Jarisch reflex was noted are summarized in Table I; it is noteworthy that in 19 of 20 times it was associated with involvement of the right coronary artery.

Patients with an occluded and recanalized coronary artery developed hypotension and bradycardia immediately after restoration of flow. When the Bezold-Jarisch reflex occurred in patients who were not recanalized or did not have an occluded "infarct" vessel, it was not associated with any particular event.

The only occurrence of Bezold-Jarisch reflex associated with LAD recanalization was observed in a patient whose LAD artery was the source of collateral blood flow to an occluded right coronary artery. In 1 patient without hypotension and bradycardia after right coronary artery recanalization, the occlusion was located distal to the origin of the posterior descending artery. None of the occluded LC arteries was of the "dominant" type.

FIGURE 1. Right coronary artery in the left anterior oblique projection showing mid-segment occlusion with an upward convexity crescent configuration.

The average time from onset of symptoms to right coronary artery recanalization was 240 minutes (range 160 to 324) among patients in whom hypotension and bradycardia developed and 195 minutes (range 125 to 236) among patients in whom they did not ($p < 0.01$.)

Three patients with recanalized right coronary arteries had had previous myocardial infarction of the inferior wall; recanalization-induced hypotension and bradycardia occurred in 2. Postural changes, atropine sulfate, or temporary pacing was used in all patients in whom hypotension and bradycardia developed. Only 1 patient required additional pharmacologic intervention.

Representative case: A 72-year-old man without a history of ischemic heart disease experienced severe retrosternal pain at 8:00 A.M. on November 7, 1982. An electrocardiogram taken at 10:30 A.M. in the emergency room showed an injury pattern in inferior leads with reciprocal changes in lateral and precordial leads. A diagnosis of acute inferior wall infarction was made and the patient was transferred to our institution for intracoronary thrombolysis. Left ventricular pressure was

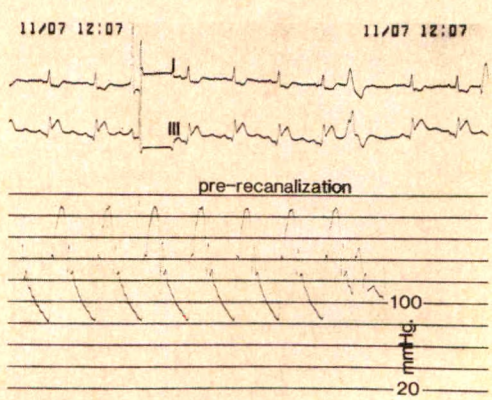

FIGURE 2. Leads I (**top**) and III; aortic pressure before recanalization.

190/26 mm Hg. Coronary arteriography revealed moderate stenosis of the LAD and LC arteries and occlusion of the right (Fig. 1). Intracoronary streptokinase infusion was started at 12:01. At 12:07, the heart rate was 75 beats/min and aortic pressure 188/82 mm Hg (Fig. 2). A sudden decrease in heart rate and aortic pressure was noted at 12:13. Contrast material was promptly injected into the right coronary artery (Fig. 3) and the occurrence of recanalization established. At 12:14 (Fig. 4), the heart rate was 54 beats/min and the aortic pressure 77/40 mm Hg. Pallor and diaphoresis were noted. Elevation of lower extremities and injection of atropine sulfate, 0.5 mg, resulted in rapid normalization. The left ventriculogram taken at the end of the procedure showed inferoposterior akinesia, with an ejection fraction of 46%. Creatine phosphokinase peaked at 865 U, lactic dehydrogenase at 241 U, and serum glutamic oxalacetic transaminase at 177 U.

Discussion

Arrhythmias associated with intracoronary thrombolysis have been reported.[8,9] The occurrence of hypotension and bradycardia after right coronary recanalization has been described recently.[10,11] Our findings are substantially parallel to those reported by Goldberg et al[10] and Wei et al,[11] particularly the close temporal relation between reperfusion of the inferoposterior left ventricular wall and clinical manifestations of the Bezold-Jarisch reflex, and confirm that myocardial reperfusion is capable of stimulating a cardiac inhibitory reflex.

Stretching due to systolic bulging of ischemic myocardium has been advocated as a possible mechanism of receptor activation.[1] However, systolic bulging of the inferoposterior left ventricular wall was never observed among the patients described in this study. Therefore, it appears that a metabolic rather than a mechanical factor initiates the Bezold-Jarisch reflex.

In this series, the Bezold-Jarisch reflex was never induced by reperfusion of the anterolateral left ventricular wall (except as described in the Results section) whereas its incidence in relation to inferoposterior reperfusion was unquestionably high. This observation confirms that in the human heart, vagal afferent receptors have an inferoposterior distribution.

Parasympathetic overactivity resulting in bradycardia or hypotension, or both, was noted in 55% of patients seen within 30 minutes of the onset of inferior wall myocardial infarction.[7] Our numerically comparable group exhibited a similar incidence after right coronary recanalization, suggesting that interruption and restoration of blood flow to the inferoposterior wall have a substantially identical effect on vagal afferent receptors.

Few patients with a nonoccluded or nonrecanalized right coronary artery developed the Bezold-Jarisch reflex. In these cases, the vagal afferent receptors might have been stimulated by changes in myocardial blood flow undetectable by arteriographic technique (possibly induced by nitroglycerin) or by contrast material.[12] Spontaneous fluctuation in discharge rate of the myocardial vagal afferent receptors was observed in the cat during prolonged ischemia.[5] A similar mechanism could conceivably operate in human subjects.

Clinical Implications

Adequate follow-up data were available in 15 patients 1 to 12 weeks after successful right coronary recanalization. Among 10 patients in whom the Bezold-Jarisch reflex developed, the pattern of inferoposterior wall contraction improved significantly in 6. Of 5 patients in whom the reflex did not develop, 3 improved. Thus recovery of left ventricular function took place in an equal percentage of patients.

If the reperfusion-induced Bezold-Jarisch reflex were to correlate with myocardial salvage, this reflex should occur with greater frequency in situations that favor a greater reduction in infarct size such as a shorter time from the onset of symptoms to recanalization. The opposite was true in our patients; that is, patients who did not manifest the reflex were among those with the shortest intervals between the onset of symptoms and recanalization. Therefore, these observations suggest that the occurrence of the Bezold-Jarisch reflex after

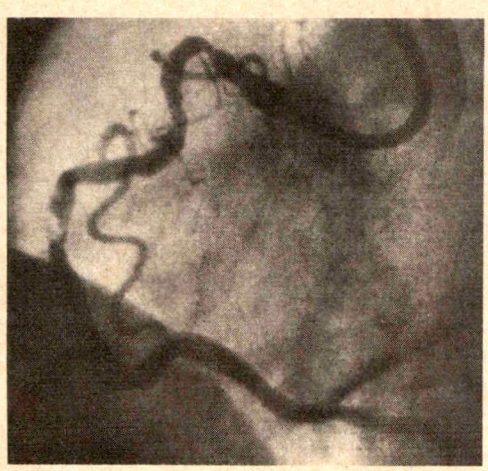

FIGURE 3. Right coronary artery in the left anterior oblique projection showing initial recanalization, but flow to posterior descending and distal right coronary artery is still minimal.

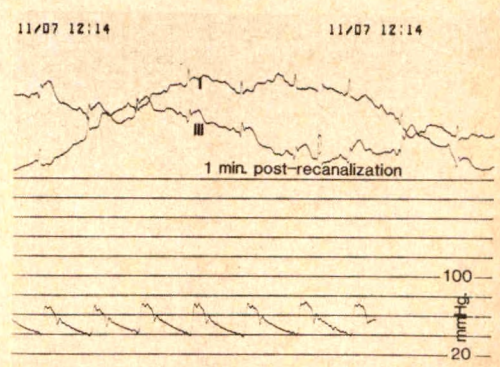

FIGURE 4. Leads I and III 1 minute after recanalization.

coronary reperfusion is not a reliable predictor of myocardial salvage.

Recently, Wei et al[13] theorized that because a reperfusion-induced cardioinhibitory reflex requires viable receptors, the adjacent myocardium is likely to be viable as well; thus, such reflex should herald myocardial salvage. Our results did not support this view, which we share conceptually. Events in the interval between evaluations of left ventricular function could conceivably have affected the extent of myocardial salvage. Further studies on this subject are needed. Because hypotension and bradycardia induced through a vagal reflex occur frequently after right coronary recanalization, it is advisable to administer atropine prophylactically to susceptible patients.

Natural History of Patients With Single-Vessel Disease Suitable for Percutaneous Transluminal Coronary Angioplasty

MARK A. HLATKY, MD, ROBERT M. CALIFF, MD, YIHONG KONG, MD, FRANK E. HARRELL, Jr, PhD, and ROBERT A. ROSATI, MD

To permit comparison of percutaneous transluminal coronary angioplasty (PTCA) with conventional therapy, the clinical outcome was established in patients who would have been suitable candidates for PTCA but who presented before the technique was available. Coronary angiograms were reviewed of patients who met the following criteria: single-vessel disease with proximal subtotal coronary stenosis, chest pain of at least class II, and cardiac catheterization before 1981. Angiograms were evaluated according to established criteria for PTCA by an experienced angiographer. One hundred ten patients (2.1% of the patient population) were judged suitable for PTCA. Clinical and catheterization findings closely resembled those of patients in the national PTCA registry. Five years after catheterization, 97% of PTCA candidates treated medically were alive and 85% had not had myocardial infarction. Forty-six patients had coronary arter bypass surgery within 6 months of catheterizatio and 10 other patients had subsequent surgery. Fiv years after surgery, 91% were alive and 87% ha not had myocardial infarction. At 6 months of fo low-up, 78% of all patients had improved at leas 1 functional class, and 86% of all patients workin before catheterization were still employed. Func tional capacity was well maintained during long term follow-up (median 6.5 years, range 1.4 t 12.2).

These data indicate that PTCA candidates hav an excellent prognosis for survival, a low risk of in farction, and well-maintained functional capacit when revascularization is reserved for those wit inadequate control of symptoms by medica therapy.

Percutaneous transluminal coronary angioplasty (PTCA) has emerged as a new and exciting therapeutic option for patients with coronary artery disease. Since Grüntzig's initial report,[1] many investigators have confirmed the technical feasibility of angioplasty.[2–7] Furthermore, objective evidence of improved coronary flow[4,5] and improved cardiac function has been pre sented.[6,7] The long-term effects of PTCA on patier survival, morbidity, and functional capacity are ur known. Hence, the relative merits of PTCA, coronar bypass surgery, and medical therapy remain uncertai To provide an appropriate standard of comparison fo patients undergoing PTCA, we determined the outcom of all patients seen at Duke University Medical Cente before PTCA became available who would have bee suitable for PTCA had they presented today.

Methods

The computerized medical information system at Duk University Medical Center used in this study contains sta dardized clinical and laboratory information collected pr spectively on all patients undergoing cardiac catheterization These patients have been followed up at regular intervals t determine survival, subsequent myocardial infarction, an functional status.

Screening criteria for the study conformed closely to th current standards for PTCA.[1,2] All patients with the followir

characteristics were identified: chest pain of New York Heart Association (NYHA) class II or greater, significant (≥75% narrowing of luminal diameter) subtotal stenosis in the proximal third of a single major coronary artery, and <75% distal coronary disease in that vessel. Only patients catheterized from 1969 through December 1980 were screened, because PTCA was begun in early 1981 at Duke University Medical Center.

Coronary angiograms from these patients were reviewed by a single angiographer (YK) experienced in performing PTCA. A coronary lesion was judged suitable for PTCA if it had the following characteristics: single, proximal, no more than slightly eccentric, not calcified, no longer than 1.5 cm, not located at or extending into branch vessels, and accessible to a dilating catheter. In addition, the vessel distal to the lesion had to be free of significant disease, and ventricular function had to be well preserved. Each characteristic was recorded separately, and an overall judgment of the suitability of both the lesion and the patient for PTCA was made.

Documentation of the functional capacity of angioplasty candidates was of particular interest in this study. The standard New York Heart Association (NYHA) classification system has been used routinely in the Duke medical computerized information system. However, a more reliable assessment of functional capacity may be possible using the recently developed Specific Activity Scale (SAS), which classifies patients by their ability to perform a set of common daily activities.[9] SAS class I indicates the least functional impairment, whereas SAS class IV indicates the most. All patients were mailed a detailed functional assessment questionnaire to supplement the routine follow-up information and to define more precisely their current functional status with the SAS. However, retrospective reclassification of previous NYHA functional assessments was not feasible. The questionnaire also determined the frequency and severity of chest pain, subsequent hospitalizations, and employment history.

Cumulative survival rates from the time of catheterization were calculated by standard life-table methods.[10] Patients treated initially with medical therapy and subsequently with coronary bypass surgery were included in the medical group until surgery. Surgical survival curves were calculated beginning the day of operation. Patients receiving bypass surgery at other hospitals were excluded from the surgical survival curves. Breslow's formulation[11] of the Cox proportional hazards model[12] was used to analyze the relation between baseline characteristics and survival.

Results

Of the 5,126 patients catheterized at Duke University for suspected coronary disease during the study period, 223 (4.4%) met the initial screening criteria. Fifteen patients were excluded from further analysis: cineangiograms could not be located for 13 patients and had deteriorated too greatly to review in 2 other patients.

Of the 208 patients whose coronary angiograms were reviewed, 110 (53%) were judged suitable candidates for angioplasty. Thus, 2.1% of the total population catheterized at Duke University Medical Center during this time period were angioplasty candidates. The reasons for excluding patients whose angiograms were reviewed are summarized in Table I. Most patients were excluded for more than 1 unacceptable angiographic finding: 27

for a single reason, 35 for 2 reasons, 27 for 3 reasons, and 9 for 4 reasons.

The baseline characteristics of patients suitable for PTCA are summarized in Tables II through IV. For comparison, these tables also present the baseline characteristics of 2 other groups: (A) the first 631 patients enrolled in the National Heart, Lung, and Blood Institute's (NHLBI) PTCA registry,[3] and (B) patients with 2- and 3-vessel coronary artery disease catheterized at Duke during the study period. The Duke PTCA candidates are quite similar to patients enrolled in the NHLBI PTCA registry.

The proportion of patients suitable for PTCA, treated medically, who were alive during follow-up is displayed in Figure 1, and the proportion without cardiovascular events during follow-up is displayed in Figure 2. Five years after catheterization 97% were alive, and 85% were alive and free of interval myocardial infarction. All deaths occurred in patients with disease of the left anterior descending coronary artery, but differences in survival according to the vessel involved were not statistically significant.

Of the 110 angioplasty candidates, 56 (51%) subsequently underwent coronary artery bypass grafting; 46 patients underwent early surgery (within 6 months of catheterization); the remaining 10 patients underwent surgery at a later time. Operative therapy in patients with single-vessel coronary disease is generally limited at Duke to those whose symptoms are not controlled sufficiently by adequate medical therapy. This policy is reflected by a significantly higher dose of propranolol received by the patients who underwent bypass surgery as compared with those who did not.

The survival curve of angioplasty candidates who underwent coronary artery surgery is displayed in Figure 3. Five years after surgery, 91% of the patients were alive and 87% were free of myocardial infarction. Two patients died within 30 days of operation; 1 died of a ruptured abdominal aortic aneurysm 9 days postoperatively, and another died of an apparent intraoperative myocardial infarction. Four patients had coronary artery surgery performed after repeat cardiac catheterization demonstrated progressive coronary disease. These 4 patients were excluded from calculations of postoperative survival, because they were no longe angioplasty candidates at the time of their operation However, 3 other patients in whom the preoperativ repeat cardiac catheterization demonstrated no chang in the suitability of the lesion for PTCA were include in the surgical survival curve. Two patients who un derwent coronary bypass surgery at other hospitals wer also excluded from the surgical survival analysis. All excluded patients were alive as of May 1982.

Patients suitable for angioplasty had a prognosis tha was indistinguishable from that of other medicall treated patients with single-vessel disease from Duke when tested univariately with the Cox proportiona hazards model.[12] Only ejection fraction was significantl related to survival among angioplasty candidates identical to the finding in the entire group of patient with single-vessel disease.[13]

Of the 46 PTCA candidates who underwent earl coronary bypass surgery, 77% were improved by 1 o more NYHA classes at the initial 6-month follow-u contact, and 67% were class I or II. However, 78% o PTCA candidates who remained on medical therap had improved by 1 or more NYHA classes at the 6 month follow-up contact, and 66% were NYHA class or II. A preliminary report from the NHLBI registry[1] indicated that 77% of patients improve after PTCA b

1 or more functional classes of the closely related Canadian Cardiovascular Society grading system.

We attempted to contact all patients and obtain detailed information about their employment history and current functional capacity. Responses were obtained from 91 of the 94 patients who were alive. Forty-eight of the 56 patients (86%) working before cardiac catheterization were still working full or part time 6 months after catheterization. Twenty-three patients ceased working before catheterization and never resumed, and 12 patients never worked outside the home.

Information about functional ability as of May 1982 was also obtained by questionnaire. The median follow-up period was 6.5 years, with a range of 1.4 to 12.2. Fourteen patients (15%) were hospitalized because of heart disease in the past year; none had a documented myocardial infarction. Thirty-four patients were still employed; 19 have been treated medically and 15 have been treated surgically. Functional capacity was assessed by the SAS: 36 patients (40%) were SAS functional class I (21 medically treated and 15 surgically treated), 30 (33%) were SAS class II (12 medically treated and 18 surgically treated), 23 (25%) were SAS class III (10 medically treated and 13 surgically treated), and 1 surgically treated patient was functional class IV. One patient refused to answer questions related to functional capacity.

Of the 110 Duke angioplasty candidates, 42 (38%) had coronary angiography repeated on a subsequent occasion. The repeat procedure was performed for a clinical indication in 34 patients and according to a study protocol after coronary bypass surgery in 8 patients. A decrease in the luminal diameter or the appearance of new lesions at subsequent coronary angiography was considered progressive coronary disease. Five of the 8 patients (62%) with repeat catheterization performed within 12 months displayed disease progression in the vessel originally involved; none had progression involving additional vessels. Ten of the 15 patients (67%) with repeat catheterization performed between 13 and 24 months displayed disease progression; 5 of these patients (33%) had progression involving additional coronary vessels. Twelve of the 18 patients (67%) with repeat catheterization performed more than 24 months after the original procedure displayed disease progression; 7 (39%) of these patients had progression involving additional coronary vessels.

Discussion

In this study we wished to characterize the natural history of patients suitable for PTCA in order to provide a standard of comparison for patients undergoing PTCA. In the absence of a randomized controlled trial, this method provides the best alternative available to judge the long-term efficacy of PTCA. We first identified all potential candidates for PTCA among patients who underwent cardiac catheterization at Duke University between 1969 and 1980. The coronary angiograms of these potential candidates for angioplasty were then carefully reviewed and their actual suitability for the procedure was established. The clinical characteristics of these patients closely resemble those of the patients in the NHLBI's registry of patients undergoing PTCA.

Our major finding was the excellent prognosis of patients suitable for PTCA. Ninety-seven percent of medically treated PTCA candidates survived 5 years. Furthermore, 85% of medically treated patients suitable for PTCA were alive and had not had myocardial infarction after 5 years of follow-up. This excellent prognosis probably results from the good left ventricular function and limited coronary atherosclerosis in PTCA candidates.[13,15] Forty-six patients (42%) underwent coronary artery bypass surgery within 6 months of cardiac catheterization, and 10 other patients underwent late operation. The 5-year survival and event-free rates in the surgically treated patients were also very good, 91 and 87%, respectively. Unfortunately, the number of patients studied does not permit any statistically meaningful comparisons between the prognosis of those treated medically and that of those treated surgically. Studies in larger groups have failed to demonstrate a difference in prognosis between medically and surgically treated patients with single-vessel disease.[13,16–18] These findings suggest that the prognosis of angioplasty candidates is indistinguishable whether angioplasty, coronary bypass surgery, or medication is chosen as therapy.

In view of the excellent prognosis of PTCA candidates, the efficacy of the procedure in improving functional capacity becomes an important consideration. Although data regarding functional status lack the precision of events such as death or myocardial infarction, they can provide a valuable perspective. The functional outcome of PTCA candidates was very good with medical therapy and subsequent coronary artery bypass surgery if needed. Seventy-eight percent of all PTCA candidates had improved by 1 or more functional classes by the 6-month follow-up contact, and 66% were NYHA class I or II. Eighty-six percent of all patients working at the time of catheterization were still employed 6 months later. Both functional capacity and employment were well maintained in most patients who initially responded to medical therapy, with only 20% later undergoing coronary bypass surgery during long-term follow-up. These findings demonstrate that good functional results can be obtained with medical therapy in many patients suitable for angioplasty.

Although many angioplasty candidates will improve with vigorous medical management, some will be refractory to therapy. The likelihood of coronary disease progression in patients with refractory symptoms may determine whether they should receive angioplasty or coronary bypass surgery. Over one-third of the PTCA candidates in this study underwent repeat cardiac catheterization on a subsequent occasion. Although no patient had documented disease progression in additional vessels in the first year, 36% of patients in subsequent years did. This figure probably represents an upper limit to the true percentage, as most of these patients were recatheterized for clinical indications such as increasing or recurring symptoms. Nonetheless, these data suggest that many PTCA candidates will ultimately require a second revascularization procedure.

As repeat coronary bypass surgery is technically more difficult and carries greater risk, angioplasty may be a better initial approach in suitable patients with refractory symptoms.

The patients described here represent a historical control group for PTCA. Such control groups are subject to several well recognized limitations. Changing diagnostic standards over time may confound comparisons when historical controls are used. Because we selected patients for this study according to current standards for PTCA, this problem has been avoided. However, indications for PTCA will broaden as experience with the procedure grows and the technique is further improved. Note that only patients with coronary lesions of ≥75% luminal narrowing were included in this series; including patients with 50% coronary lesions would have improved the observed outcomes.[19] Evolution of therapeutic methods also limits the utility of historical comparison groups. New drugs have been introduced (such as calcium channel blocking agents), surgical methods have been refined (such as cardioplegia), and total cardiovascular mortality has declined over the past 12 years; these and other developments may also confound our findings. However, therapy has probably improved over this period, and PTCA candidates probably would receive better care and experience better outcomes today than are reported here.

This study used an observational data bank that included patients seen at 1 institution over a 12-year period. The advantages and limitations of this approach are widely recognized.[20] The clinical management of these patients was the responsibility of several cardiologists, and no strict protocol was followed. Consequently, the independent effect of any 1 component of therapy on functional capacity cannot be completely separated from another. For instance, the clinical outcome of patients maintained on medical therapy may have been influenced by the availability of coronary bypass surgery for those whose symptoms cannot be controlled adequately. Conversely, the clinical outcome of patients who underwent coronary artery bypass grafting may have been affected by the availability of medical therapy before and after the operation. Our findings do support the value of the conservative therapeutic approach generally followed at Duke University Medical Center that consists of adequate medical therapy and subsequent revascularization if needed in patients with single-vessel coronary artery disease.

Introduction of a new therapeutic method usually prompts calls for a randomized, controlled trial to judge its efficacy. Our findings imply that very large sample sizes are necessary for a randomized trial of PTCA, as undesirable outcomes occur so infrequently in suitable patients. For instance, a trial randomizing a total of 7,600 patients would have only an 80% chance of documenting an actual 33% reduction in mortality over 5 years (that is, alpha = 0.05, beta = 0.80). A total of 1,400 patients would have to be randomized to document a 33% reduction in cardiac events at the same level of reliability. More patients are required to detect smaller reductions in event rates or to attain higher reliability. Such a trial would be very expensive and would take years to complete. Meanwhile, the techniques of PTCA, coronary bypass surgery, and medical therapy woul continue to evolve, reducing the relevance of the trial findings. Thus, a randomized trial of PTCA with deat or myocardial infarction or both as a primary end poir seems highly impractical. However, a trial with en points such as left ventricular function, exercise ca pacity, or medical costs should require fewer patient and less time; such a trial may be feasible.

Detrimental Effect of Propranolol in Patients With Coronary Arterial Spasm Countered by Combination With Diltiazem

PIERRE Y. TILMANT, MD, JEAN M. LABLANCHE, MD, FRANÇOIS A. THIEULEUX, MD, BERNARD A. DUPUIS, MD, and MICHEL E. BERTRAND, MD

This study determines, with quantitative variables, if propranolol is detrimental in patients with documented coronary arterial spasm and if this drug can be used in combination with calcium antagonists. Eleven patients with documented coronary spasm were entered prospectively in a study with 4 phases of 2 days each: (1) control, (2) diltiazem or propranolol (mean 225 ± 75 mg/day), (3) propranolol or diltiazem (360 mg/day), (4) propranolol and diltiazem. The effects of the drugs were assessed by the detection of ischemic electrocardiographic episodes (24-hour electrocardiographic monitoring) and provocative tests with ergonovine. During the period of treatment with propranolol, the number and the duration of attacks increased and provocative tests had positive results in all patients. Diltiazem completely abolished spontaneous episodes, but 6 of 11 patients remained sensitive to the administration of ergonovine. The association of the 2 drugs led to a disappearance of ischemic episodes. In conclusion, propranolol is ineffective in patients with coronary artery spasm. It can be used in combination with diltiazem, but without any advantage over diltiazem alone.

The efficacy of beta-adrenoreceptor blockers in effort angina is well established. However, the effect of beta blockade on coronary artery spasm is controversial. In 1971 and 1975, Guazzi et al[1,2] reported a reduction in the number of attacks of variant angina in patients who received a large dose of beta-blocking drugs. Other investigators[3–6] have reported that propranolol was detrimental in the treatment of coronary artery spasm. The purpose of this study was to establish the effects of propranolol in patients with documented coronary artery spasm, to compare this drug with diltiazem, a calcium antagonist, and to evaluate the effects of the 2 drugs combined.

Methods

We studied 11 patients (10 men and 1 woman) aged 43 to 69 years (mean age 50). They had angina at rest with ≥1 mm of S-T segment elevation during the attacks. Five patients also had angina on effort. Coronary arteriography showed significant (>75%) vessel disease in 6 patients; however, only small irregularities or normal vessels were noted in 5 patients. All of these patients had a coronary arterial spasm documented by coronary arteriography and defined as a transient, reversible subtotal or total narrowing of a major epicardial coronary branch associated with objective evidence for myocardial ischemia. Spasm was located on the right coronary artery in 6 patients, on the left anterior descending coronary artery in 2, and on the circumflex branch in 3.

The patients were studied over 9 days. The study consisted of 4 phases (Fig. 1). Phase 1 consisted of 2 days without treatment (control period). At the end of this phase, the patients were randomized to therapy with propranolol or diltiazem during the 2 days (Phase 2). They were then crossed over to the opposite drug regimen (Phase 3). Between Phases 2 and

TABLE I Clinical Data and Results of 24-hour Holter Monitoring

Patient	Age (yr) & Sex	Vessel Disease	Location of Coronary Spasm	Number of Ischemic Episodes in Phases			
				1	2	3	4
1	45M	1	Right	3	6	0	0
2	45F	NS	LAD	2	6	0	0
3	49M	1	LC	4	5	0	0
4	52M	NS	Right	5	4	0	0
5	48M	NS	LC	4	4	0	0
6	48M	1	LC	5	5	0	0
7	69M	2	Right	7	10	0	0
8	43M	3	Right	4	4	0	0
9	41M	NS	LAD	3	7	0	0
10	50M	NS	Right	6	6	0	0
11	60M	1	Right	3	6	0	0

LAD = left anterior descending coronary artery; LC = left circumflex branch; NS = nonsignificant stenosis; Right = right coronary artery.

3, there was 1 day without treatment to wash out the effects of the drug. During Phase 4, the patients received the 2 drugs over 2 days. The dosage of propranolol (225 ± 75 mg/24 hours, mean ± standard deviation) was adjusted to obtain a heart rate of 50 to 60 beats/min. Diltiazem was given in a standard dosage of 360 mg/24 hours. During Phase 4, the patients received a high dose of diltiazem (60 mg 6 times a day) and propranolol at the same dose as in Phase 1. During each phase, a 24-hour ambulatory monitoring was recorded on day 1 and 2. The monitoring was performed in 2 leads (CM5—manubrium; V_5 and C′M5—manubrium V_{5R}). Ischemic episodes were detected by S-T segment changes (decrease or increase) >1.5 mm. The results were assessed by the number, the duration of ischemic episodes, and the presence or absence of arrhythmias. Mean heart rate during the day was also calculated. On the second day of each phase, a provocative test with ergonovine was performed at 11:30 A.M. The tests started with an intravenous injection of 0.1 mg of methylergonovine. In the absence of electrocardiogram changes, a second dose of 0.2 mg was injected 5 minutes later; if there was no response, a third (0.3 mg) and a fourth dose (0.4 mg) were administered at intervals of 5 minutes. The electrocardiogram (12-lead) was carefully monitored and the criterion for a positive test was an S-T segment change >1 mm. The test was considered to be negative if 10 minutes after the last injection (1 mg = 0.1 + 0.2 + 0.3 + 0.4) the electrocardiogram was unchanged. If the test showed S-T segment changes >1 mm, intravenous isosorbide dinitrate (3 mg) was immediately injected. This procedure resulted in no complications.

The results of ergonovine testing were compared with 2 statistical tests. Since the variable was neither continuous nor normally distributed, a nonparametric test was required, and the chi-square test was used; but in the patients whose tests had positive results during treatment, a comparison of dose levels was performed with a paired *t* test.

Results

Effects on heart rate: Mean heart rate during the day was significantly lower in Phases 2, 3, and 4 than during the control period (Phase 1). When the patients received propranolol, the mean heart rate was 53.6 ± 8.6 beats/min. Diltiazem also decreased heart rate (from 77.3 ± 12.4 to 64.1 ± 8.2 beats/min, $p < 0.01$). When propranolol and diltiazem were used, heart rate decreased 48.8 ± 3.1 beats/min. This tendency to bradycardia could be a limitation to the use of this drug combination.

Comparison of Phase 1 (control period) an phase of propranolol treatment: During the contr period, 46 attacks were detected by Holter monitorin (Table I) over a period of 150 minutes for the whol group. Seven attacks were complicated by arrhythmia (run of premature ventricular beats). Some patients ha more attacks with propranolol treatment than durin the control period, but others had fewer ischemic ep sodes with propranolol. For the group, the number attacks increased from 46 to 63 and the total duratio reached 235 minutes during the phase with propranolo Six attacks were complicated by runs of prematu ventricular beats; one patient had a short run of ver tricular tachycardia. Provocative tests always ha positive results during the control period and the mea dose of ergonovine inducing S-T segment changes > mm was 0.47 ± 0.09 mg. The amplitude of S-T segmer changes was 2.18 ± 0.81 mm (mean ± standard error the mean). During the period of treatment with pr pranolol, the tests had positive results in all patient (Table II). The dose of ergonovine (0.49 ± 0.17 mg) wa not significantly different from the dose during th control period. The maximum amplitude of S-T seg ment changes (3.4 ± 0.72 mm) was higher ($p < 0.0$ during treatment with propranolol than during th control period. Thus, the 24-hour ambulatory mon toring clearly showed a detrimental effect of propra olol. However, the provocative test, which had positiv results in all patients, demonstrated a similar reactivit of the patients with propranolol and during the contr period.

Comparison of Phase 1 (control period) an phase of diltiazem treatment: Provocative test result were significantly different (chi-square = 6.97, $p < 0.0$ during the 2 periods; when the patients were treate with diltiazem, the ischemic episodes totally disap peared and Holter monitoring did not reveal S-T seg ment changes or arrhythmias (Table I). The test ha negative findings in 5 patients but had positive result in 6 patients (Table II). In this latter group, the dose ergonovine inducing positive test results (0.48 ± 0.1 mg) was slightly but insignificantly higher than durin the control period (0.37 ± 0.08 mg). Thus, from thes results, we conclude that diltiazem was very effectiv and completely abolished spontaneous ischemic epi

Dose = dose of ergonovine; SEM = standard error of the mean; S-T↑ = S-T segment elevation (mm); + = positive test result; − = negative test result.

sodes; but at a dose of 360 mg/day, 6 of 11 patients remained sensitive to the administration of ergonovine. No adverse effects were observed during the short period of treatment with diltiazem.

Results of treatment with diltiazem and propranolol combined: The combination of diltiazem and propranolol led to a disappearance of ischemic episodes on 24-hour electrocardiographic monitoring. No S-T segment changes or arrhythmias were observed (Table I). During the provocative tests, only 3 patients had a negative test result and 8 had a positive test. However, the dose of ergonovine inducing S-T segment changes >1 mm (0.71 ± 0.1 mg) was higher during treatment with propranolol and diltiazem than during the control period (0.44 ± 0.1 mg) ($p < 0.05$) (Table II). If we compare propranolol alone with propranolol and diltiazem, the combination is better. The ischemic episodes disappeared but the chi-square test did not show a significant difference in the provocative test results. However, the question arises as to the advantages of diltiazem and propranolol over diltiazem alone. The Holter monitoring findings revealed no difference. However, the provocative test findings revealed that the 6 patients whose test results were positive during treatment with diltiazem had positive findings when this drug was used with propranolol. (Two had positive results with the same dose of ergonovine, 3 with a higher dose, and 1 with a lower dose.) However, 2 tests that had negative results during treatment with diltiazem alone had positive findings with propranolol and diltiazem. In fact, for the whole group, there was no significant difference for the dose of ergonovine inducing S-T segment changes in each phase (diltiazem alone versus propranolol and diltiazem). Finally, we can conclude that the combination of propranol and diltiazem has no apparent advantage over diltiazem alone. No adverse effects were observed with the combination of propranolol and diltiazem, but heart rate decreased to 48.8 ± 3.1 beats/min.

Discussion

The evaluation of a treatment in patients with coronary arterial spasm is very difficult. The results must be interpreted with caution because of the wide spontaneous variability of symptoms. Patients with vasospastic angina can have frequent attacks during the active phase of the disease, while the attacks disappear during a quiescent period. Thus, the effects of a drug must be assessed over a short period. Moreover, the trials had to take account of the frequency of asymptomatic ischemic episodes.[7] Sixty-four percent of ischemic episodes demonstrated by 24-hour electrocardiographic monitoring are asymptomatic[8]; in general, S-T segment changes are symptomatic if they persist for >3 minutes but are asymptomatic if they are shorter.[6] Thus, the evaluation of the effects of drugs in coronary arterial spasm requires a trial of short duration in order to study the patients in active phase and with objective tests. Holter monitoring can detect spontaneous ischemic episodes (even though asymptomatic) and provocative tests (with incremental doses of ergonovine) can assess the reactivity of the patients. Some workers[9] have questioned the reproducibility of the test; others[10] consider the provocative test reproducible and a good means of assessing the efficacy of a drug. In our study, the protocol lasted 9 days and the assessment was made with objective tests.

Propranolol leads to reduction in heart rate, blood pressure, and myocardial contractility, decreasing myocardial oxygen demand. In patients with angina related to coronary artery spasm, Maseri et al[11] demonstrated that myocardial oxygen demand was unchanged before the attack and that ischemia results from a decrease in myocardial oxygen supply. Thus, it is illogical to treat such patients with beta-blocking agents. However, the direct effect of beta blockers on vascular receptors can play an important role because beta-adrenergic blockade can unmask alpha-adrenergic vasoconstriction. Some investigators[12,13] have suggested that an increase of sympathetic activity with a stimulation of alpha adrenoreceptors can induce coronary artery spasm. Ricci et al[14] reached the same conclusions in relieving spasm with phentolamine or preventing the recurrence of attacks with phenoxybenzamine. However, Robertson et al[15] found no modification of various indexes of sympathetic nervous system function in patients with Prinzmetal's variant angina. Thus, theoretically, the beta-blocking agents can indirectly induce

a more intense vasoconstriction and are contraindicated in patients with coronary artery spasm. Clinically, there are controversial results with propranolol in patients with Prinzmetal's variant angina. Guazzi et al[16] reported satisfactory results in patients with variant angina; beta blockers fully abolished the symptoms in 73% of the cases as evaluated in subjective (pains reported) and objective terms (ECG alterations documented during continuous recordings). However, the doses of propranolol were very high (mean 390 mg/day, range 160 to 800).

In contrast, several reports[17,18] detail poor results with propranolol. More recently, Robertson et al,[6] using a double-blind protocol with quantification of ischemia by electrocardiographic recording, showed that at low doses (40 mg every 6 hours) or high doses (160 mg every 6 hours), the duration of attacks was significantly prolonged, but the frequency was not. In our study assessing propranolol with quantitative variables, the number and the duration of the attacks were significantly higher during the treatment with propranolol than during the control period. In contrast, the response of the patients to ergonovine was not significantly different. Consequently, we agree with the conclusions of Robertson et al[6] that propranolol as the only therapy is frequently detrimental in angina due to coronary artery spasm and should not be used alone in the treatment of this disorder.

In contrast, calcium antagonists are very effective.[19,20] In our study, we observed that diltiazem completely abolished the ischemic episodes. However, in contrast to the disappearance of ischemic episodes, ergonovine tests had positive results in some patients. Obviously, it can be argued that ergonovine is an artificial means of provoking spasm and that the disappearance of attacks on electrocardiographic monitoring means that the drug is really very effective; however, in some patients the reactivity of the vessel to ergonovine persists despite treatment.

The combination of propranolol and calcium antagonists can logically be used in patients with spasm superimposed on organic fixed narrowing who have angina at rest and on effort. In our study, the combination of propranolol and diltiazem had the same effect as diltiazem alone on the spontaneous ischemic episodes. However, we did not perform exercise tests during the control period and the phase with both drugs combined. This investigation should be of interest in evaluating the effects of exercise capacity, especially in the patients with fixed organic narrowing. Although we did not observe spontaneous ischemic episodes with combined treatment by diltiazem and propranolol, in addition to the 6 patients with a positive ergonovine test resu during diltiazem therapy, 2 other patients became r active to ergonovine.

Long-Term Prognosis After First Q-Wave (Transmural) or Non–Q-Wave (Nontransmural) Myocardial Infarction: Analysis of 593 Patients

RONALD J. KRONE, MD, ELLEN FRIEDMAN, MS, SAMER THANAVARO, MD, J. PHILIP MILLER, AB, ROBERT E. KLEIGER, MD, and G. CHARLES OLIVER, MD

Follow-up results in 593 patients ≤7 years (mean 4.7) after hospital discharge for their first myocardial infarction (MI) are presented. Patients were grouped according to the presence or absence of Q waves on electrocardiograms after the MI and by peak serum glutamic oxalacetic transaminase (SGOT) level during hospitalization. Cardiac mortality varied. Patients with Q-wave infarcts and an SGOT level ≤240 IU/liter had a cardiac mortality of 3.1% per year, whereas patients with Q-wave MI and an SGOT level >240 IU/liter had an 11% 6-month mortality and a 3.8% per year cardiac mortality thereafter. However, patients with non–Q-wave (nontransmural) MI had a excellent survival rate for 2 years (96.8%) which continued in patients aged ≤60 years thereafter. However, patients with non–Q-wave infarcts aged >60 years had a 12% per year cardiac mortality in the third post-MI year and an additional 12% died each year thereafter. Early mortality was related to enzyme level, whereas late mortality was a function of type (Q-wave or non–Q-wave) and age.

The prognosis of patients discharged from the hospital after a first non–Q-wave (nontransmural) or Q-wave (transmural) myocardial infarction (MI) has been the subject of numerous studies,[1–6] but the findings have been largely inconclusive and conflicting. However, in many studies, either the number of patients with nontransmural MI was small (<25)[1,4] or a substantial percentage of patients with previous MI[2,3,6] were included. Mahony et al[1] recently showed that the prognosis of patients with nontransmural MI and no previous MI was much better than that of patients with nontransmural MI who had had a previous MI. Thus, separating patients with a first MI from those with multiple MIs seems one way of deriving meaningful findings.

We previously showed that patients with first non–Q-wave (nontransmural) MI usually had a relatively small MI and a lower in-hospital mortality rate than patients with Q-wave (transmural) MI.[7] The present study establishes the prognosis of patients after hospital discharge for their first Q-wave or non–Q-wave MI. Features of the original MI which are useful in predicting survival over this period are identified.

Methods

Criteria for selection: Subjects were selected from consecutive patients aged ≤75 years admitted <48 hours after MI to the coronary care unit at either the Jewish Hospital of St. Louis or Barnes Hospital between November 1971 and June 1975. The age limit was selected to focus on persons who might be candidates for aggressive management of their coronary disease. Patients were excluded if there was any evidence of previous MI or if they had persistent left bundle branch block. All patients' electrocardiograms were continuously monitored for the first 3 days of hospitalization and standard 12-lead electrocardiograms and serum enzyme levels (creatinine kinase [CK], serum glutamic oxalacetic transaminase, aspartate transaminase, [SGOT], lactate dehyrogenase [LDH], and heat stable LDH or alpha hydroxy butyl dehydrogenase) were obtained daily for 3 days according to a prescribed protocol.

The diagnosis of MI was made if these 2 criteria were met: (1) a clinical history compatible with MI, and (2) serum enzyme changes typifying MI with at least 1 value exceeding 1.5 times the upper limits of normal. The electrocardiographic diagnosis of Q-wave MI required pathologic Q waves (0.04 second in duration and amplitude >25% of the R wave) or, for

posterior MI, pathologic R waves (0.04 second in duration with RV_1/SV_1 or $RV_2/SV_2 > 1$), these changes associated with evolving ST-segment and T-wave changes in appropriate leads.[8] The diagnosis of non–Q-wave MI was made when the electrocardiogram did not meet QRS criteria for Q-wave MI but history and enzymes confirmed the presence of acute infarction.

Data management: Demographic and clinical information was obtained prospectively[7] from the patients' charts as well as from direct patient interviews by trained personnel following a protocol. Records were analyzed using the Statistical Analysis Systems computer program.[9] The data were subjected to rigorous checks of consistency, and when questions arose, the patients' charts were reviewed. All electrocardiograms were reviewed by 2 of us (RJK, ST) independently to confirm the classification of MI.

Follow-up information was obtained by telephone or mail, first from the patient's physician and then, if necessary, from the patient. If a patient had died, the circumstances of the death were ascertained from family members or neighbors.[10] Death was classified by a panel of 4 cardiologists as: sudden death, sudden death/new MI, not sudden death/new MI, not sudden death/cardiac death, and noncardiac death. A new MI had to meet the same criteria as the index MI, from a review of hospital records or proof at postmortem examination. Deaths within 1 hour of the onset of symptoms and unexpected, unobserved deaths were classified as sudden.

Statistical methods: Demographic and clinical characteristics of patients with Q-wave and non–Q-wave MI were compared with Fisher's exact test (Table I). The log transforms of peak SGOT and peak LDH levels and mean ages for the 2 groups were compared using a 2-sample *t* test (Table I). Cardiac survival rates were plotted for the follow-up period by the method of Kaplan-Meier, with noncardiac deaths treated as censored data.[11,12]

The overall survival rate of patients with the 2 types of MI over the follow-up period was evaluated using Breslow's test for equality of survivorship functions.[12,13] The probability of death of patients in different subgroups at different time periods for the first 3 years was examined by performing 4 separate although nonindependent log rank tests[14] over the convenient intervals of 0 to 6, 6 to 12, 12 to 24, and 24 to 36 months (Table II). This analysis was not continued becau of large numbers of censored patients after 3.5 years. Howev the survival curves are carried out to 6 years (Figs. 1 to 4).

The prognostic value of various demographic and clinic variables obtained at the time of MI was assessed for the fi follow-up year and again for the third year (Table III). T variables chosen for analysis from the many available we those previously associated with post-MI mortality[7,15–20] those that reflected our interest in the type and size of i farction. Cardiomegaly was assessed from the admissi (usually portable) chest roentgenogram.

Multivariate analysis was carried out in a stepwise fashi using the Cox regression model.[21,22] Briefly, an unadjust chi-square statistic (Q statistic) was computed to assess t relationship between each variable and cardiac survival. T variable with the largest Q statistic (best relation) was add to the model and chi-square Q statistics, adjusted for variabl in the model, were computed for all variables not in the mod The variable with the largest adjusted Q statistic was th introduced into the model and the procedure repeated un no remaining variable contributed independent informati significant at the $p < 0.05$ level (Table IV).

Results

Study population: Five hundred ninety-three p tients aged ≤75 years were discharged after their fir MI and met criteria for our study. There were 499 p tients with Q-wave MI (84.2%) and 94 patients wi non–Q-wave MI (15.8%). Three patients with Q-wa MI were lost to follow-up during the first 3 years, givi a 99.5% complete follow-up for the first 3 years. T mean follow-up was 4.7 years and 175 patients we followed up for 6 years. The 3-year mortality was 19.6 (116 patients) overall, 20% of the group with Q-wave M (100 patients), and 17% of the group with non–Q-wave (16 patients).

Patients in both groups were similar with respect age, sex, race, and coronary risk factors (Table I). P tients with Q-wave MI had significantly higher pea SGOT and LDH levels than did those with non–Q-wa

MI (p = 0.0001). Because peak enzyme levels are associated with infarct size,[20] we stratified patients according to peak SGOT level obtained, choosing 240 IU/liter as the cutoff point. We had previously found that this value separated patients into 2 groups with distinct in-hospital clinical courses.[7] All but 9 of the patients with non–Q-wave infarction had peak SGOT levels <240 IU/liter.

AV block = atrial ventricular block; BUN >25 = urea nitrogen, >25 mg/dl on hospital admission; CHF = congestive heart failure; FIBFLUTTER = atrial fibrillation or atrial flutter; IVCD = intraventricular conduction defect; LLDH = log 10 peak lactose dehydrogenase; LSGOT = log 10 peak glutamic oxalacetic transaminase (aspartate transaminase); PREVHT = a history of hypertension before initial infarction; PVCS = premature ventricular complexes; SUPRAVB = supraventricular beats.

Relation of type of infarction to new infarction within 60 days: Nine survivors of Q-wave MI (1.8%) had a second MI within 60 days of the index MI, and 3 of them died within 3 years. Seven patients with non–Q-wave MI (7.4%) had a new MI within 60 days of the first (p = 0.0136 relative to Q-wave MI) and 5 died within 3 years.

Effect of infarction type and estimated size on cardiac mortality: Figure 1 shows the cumulative cardiac survival in patients with Q-wave and non–Q-wave MI. The overall survival distributions of both groups of MI were not different. After stratifying the patients by peak SGOT, the differences in survival after each type of MI become clear (Table II, Fig. 2)(p = 0.007). (Among the 9 patients with non–Q-wave infarction and an SGOT level >240 IU/liter, there was only 1 death in the first years, so that all non–Q-wave MIs were combined into 1 group). Comparing cardiac mortality using the log rank test (Table II) over the first 3 years showed a marked difference in cardiac mortality rate (p = 0.0001) for the first 6 months among the 3

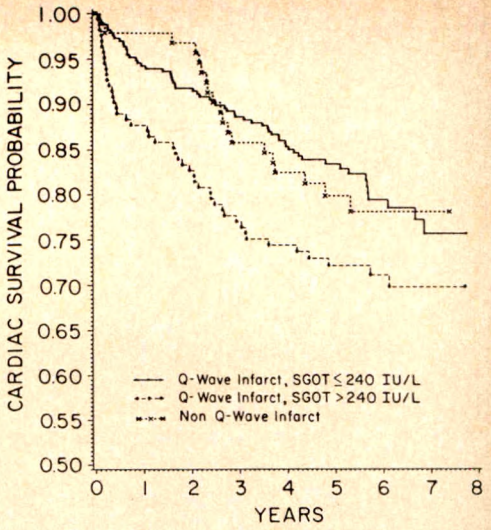

FIGURE 2. Cardiac survivorship of patients with Q-wave infarctic subgrouped by serum glutamic oxalacetic transaminase (SGOT) lev greater or less than 240 IU/liter compared with non–Q-wave infarctio Note the high early mortality in Q-wave infarctions with peak SGC >240 IU/liter and the high late mortality in non–Q-wave infarctions

groups. Patients with Q-wave MI and peak SGOT levels >240 IU/liter had a worse prognosis in the first 6 months than did those with either non–Q-wave or Q-wave MI with peak SGOT levels ≤240 IU/liter. From 6 months to 2 years after MI, survival in all 3 groups was similar. However, in the third year significantly more cardiac deaths occurred in patients with non–Q-wave MI (11.2% of the original number) than in those with Q-wave MI and SGOT levels ≤240 IU/liter (3.4%) or those with Q-wave MI with SGOT levels >240 IU/liter (6.8%). The survivorship curves (Fig. 2) demonstrate the different time course of survivorship for the different types of MI in the first 6 months and again in the thir year. The incidence of sudden death in these group generally paralleled the incidence of cardiac death fro all causes. Of the 50 sudden deaths in all patients in th first 3 years, 20 were unexpected and unwitnessed.

Contribution of other variables to mortality (Co model): We used a log rank test to assess the prognost significance of the demographic and clinical variable The univariate relations to cardiac death in the first an third year are shown in Table III. With the exceptio of cardiomegaly and age, most variables of significar

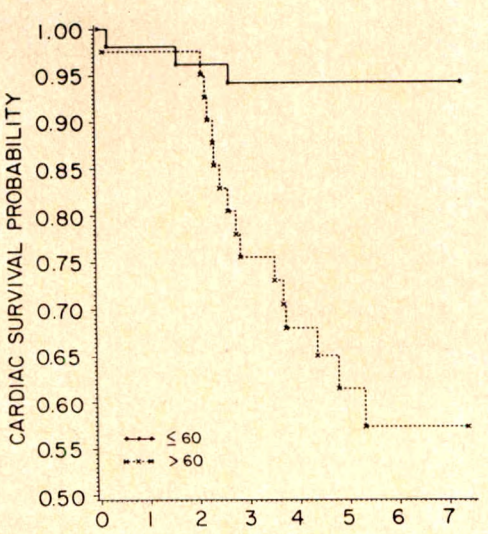

FIGURE 3. Cardiac survivorship in patients with non–Q-wave infarction subgrouped by age ≤60 or >60 years. There were 41 patients aged ≤60 years and 53 patients >60 years. Forty-five patients ≤60 years were followed up to death or to 4 years and 23 patients >60 were followed up 4 years. There were no deaths recorded in the ≤60 group after 3 years.

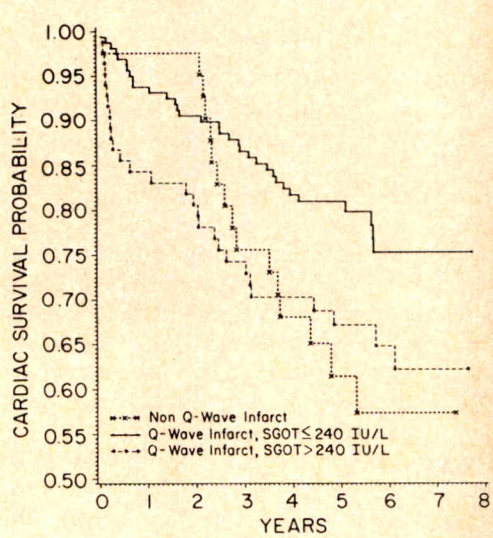

FIGURE 4. Cardiac survivorship in patients aged >60 years subgroupe by type of infarction and peak serum glutamic oxalacetic transaminas level (SGOT). The mortality of patients with non–Q-wave infarctio exceeds that of any other group 4 years after infarction.

prognostic value for death in the first year were not prognostic for death in the third year.

We used a stepwise procedure to fit a Cox model to assess the unique contribution to prognosis of a variable after considering the relation of other variables with stronger associations. The final result of the Cox model shows the independent predictors of death in the first and third years (Table IV). Most of the first year predictive variables can be associated with an extensive amount of infarcted myocardium. In contrast, in the third year, the type of MI (non–Q-wave) was the best independent predictor of cardiac mortality ($p = 0.0028$) and only the age and peak LDH level had additional predictive power (Table IV).

The possibility that the mortality of patients with non–Q-wave MI in the third year was due to an increased incidence of new infarctions occurring in the first 2 years was also examined, but no relationship was found. Of the 10 cardiac deaths in the third year, only 1 patient had a new MI in the first 2 years. Two patients had had a new MI 30 days before death and the remaining 7 patients did not have a documented new MI before death.

Importance of age: Increasing age was associated with a higher cardiac mortality in the patient population as a whole (Tables III and IV). When patients were grouped by both age (≤60 and 61 to 75 years) and type of MI, and Q-wave MI grouped by peak SGOT level, life-table curves showed that older patients had the highest cardiac mortality in both subgroups of Q-wave infarcts. This finding was especially marked in patients with non–Q-wave infarcts (Fig. 3, $p = 0.001$). Patients in both age groups had excellent survival in the first 2 years after infarction. Younger patients continued to have excellent survival, whereas older patients began to demonstrate a very high incidence of cardiac death after 2 years. By 4 years after infarction, cardiac survivorship in this group was the poorest of that in any group (Fig. 4).

Discussion

The terms *transmural infarction* and *nontransmural infarction* have been used for many years in the electrocardiographic classification of MI and continue to be used even though evidence indicates a poor correlation with pathologic findings.[23] MI without Q waves on the electrocardiogram may be transmural on pathologic examination and the reverse is also true.[24] In the present study, we showed that the distinction between Q-wave and non–Q-wave infarction is prognostically useful even though it may not be pathologically accurate.

We previously showed that in persons with a first infarction, those developing Q waves had a worse in-hospital prognosis than did patients who did not (11 versus 3%, $p = 0.007$).[7] Non–Q-wave infarctions released less enzyme and therefore were presumably smaller, which could account for the better in-hospital prognosis of these patients.

The present study shows that the long-term prognosis of patients after a first MI depends on the development or nondevelopment of Q waves, the peak level of enzymes released, and the patient's age. The largest division of our patients (the 56.6% in whom Q waves developed and who had an SGOT level <240 IU/liter) demonstrated a yearly cardiac mortality of 3.1% of the original survivors after 6 months, which continued at about the same rate thereafter. In that same group, patients aged >60 years had a slightly greater mortality (3.8% of the original survivors per year versus 2.9% of the original survivors per year in patients ≤60 years) ($p = 0.1629$). Patients with a presumably larger MI and Q-wave infarcts with SGOT levels >240 IU/liter had a very high mortality in the first 6 months after infarction (11%). However, after 6 months, cardiac mortality was steady at 3.8% of the original group per year thereafter, just slightly worse than the continuing mortality of the remainder of the patients with Q-wave MI and SGOT levels ≤240 IU/liter.

The experience of patients with non–Q-wave MI was totally different. For the first 2 years they experienced excellent survival (96.8%, a cardiac mortality of 1.6% per year), but beginning in the third year the older patients had a very high rate of cardiac death (12% of the original group per year) which 0ontinued for the duration of follow-up (Fig. 3). By the end of the fourth year, cardiac survival in this group was the lowest of that of any of the subgroups and remained so for the duration of follow-up (Fig. 4).

The survival curve for our patients with a first Q-wave MI is identical to that calculated from the data of Bland and White by Zumoff et al.[25] Cardiac mortality in these patients can be described by 2 superimposed survival curves, a fast component curve and a slow component curve. Our data suggest that the fast component or the worst mortality curve reflects the contribution of larger MIs, whereas the slower component mortality curve is a feature of all Q-wave MIs after 6 months. The non–Q-wave MI follows a totally different survival curve. Young patients have an excellent overall survivorship for at least 4 to 5 years after the initial MI, whereas older patients have an initially good survivorship but after 2 years have a very high cardiac mortality.

Parameters that defined the group at high risk in the first year after MI are similar to variables that influence acute in-hospital mortality[7,17–20] and reflect increased myocardial damage. The Q-wave feature of the MI was predictive of cardiac mortality simply because the Q-wave MI was generally larger than the non–Q-wave infarction.[7]

The mechanism of death beginning in the third year in older patients with non–Q-wave MI is not clear. Most cardiac deaths in our study were sudden, occurring within 1 hour of symptoms or unobserved. The role of ischemia in initiating what in most cases is probably an arrhythmic event is yet to be defined.[26] Hutter et al[6] reported a high incidence of angina (62%) in their patients with "nontransmural infarction" (46% of whom had a previous MI), but the relation between post-MI angina and subsequent mortality was not commented upon. Coronary angiography in patients with non–Q-wave MI has shown that the underlying coronary artery disease is as severe as that in patients with Q-wave MI,[27–29] but there is less ventricular damage. Older patients with non–Q-wave MI may have areas of

"jeopardized myocardium" [30] perfused by diseased vessels which may be at risk of sudden occlusion by thrombus or intimal hemorrhage[26] in the future. The higher incidence of a second MI within 60 days of the initial non–Q-wave infarction is consistent with this hypothesis.

We have shown that survival after a first MI is related to the appearance of Q waves. Early mortality (<6 months) reflects the amount of myocardial damage. Late mortality is not as strongly related to the amount of damage, but is strongly related to age >60 years and the absence of Q waves during the original MI. We have identified a group at special risk for mortality late after the first MI, that is, patients >60 years with non–Q-wave MI, and a low-risk group, that is, younger patients (≤60 years) with non–Q-wave infarcts. Procedures that attempt to delineate potentially ischemic myocardium in survivors of the index MI, such as standard stress testing, thallium stress testing, exercise radionuclide ejection fractions, and even coronary angiography, would appear indicated after most MIs, but the available data do not indicate whether this testing early after MI will identify persons at risk of dying after 2 years. Until more information is available, periodic reevaluation at intervals in these patients seems prudent, especially in older patients with non–Q-wave MI.

Acknowledgment: We wish to thank Linda Brandenburger, RN, and Jane Humphrey, RN, for their diligence in obtaining the excellent follow-up, and Michael Province MS, for additional help with statistics. We would also like to thank Kim VanHollenbeck for typing this manuscript and James Havranek for editorial assistance.

Periods of Differing Mortality Distribution During The First Year After Acute Myocardial Infarction

ELIZABETH A. GILPIN, MS, JAMES A. KOZIOL, PhD, ERLING B. MADSEN, MD, HARTMUT HENNING, MD, and JOHN ROSS, Jr, MD

The mortality rate after acute myocardial infarction (AMI) has generally been modeled by a single exponential function. The present study was undertaken to determine, in 3 different populations, whether or not periods exist during the first year after AMI which have mortality distributions that differ from this pattern. The 3 patient populations included San Diego (346 patients, 71 deaths), Vancouver (704 patients, 146 deaths), and Copenhagen (1,140 patients, 262 deaths). Hospital admission was within 24 hours of the onset of symptoms, and patients dying within the first 24 hours after hospital admission or of noncardiac or unknown causes were not analyzed. The mortality between 2 and 21 days in the combined data base was 11.4% (range 10.9 to 11.7) and from 3 weeks to 1 year 10.5% (range 9.0 to 11.3). A high degree of similarity was noted among the shapes of the 3 survival curves. The hypothesis of an exponential mortality rate during the entire first year was rejected. Using a special statistic, changepoints at days 17, 23, and 24 in the 3 populations (21 days for the combined data base) were identified and used thereafter to divide the year into 2 separate periods of mortality within which exponentiality for the mortality rate was not rejected. The point by which exactly 50% of deaths had occurred was day 19, with 75% of deaths occurring by day 100. These data further define the natural history after AMI and indicate optimal follow-up periods for short- and longer-term management strategies based on risk assessment or trials of risk reduction after AMI.

Mortality after acute myocardial infarction (AMI) has often been modeled by an exponential distribution,[1,2] but detailed analysis of the shapes of survival curves has not been reported. If changepoints could be identified, differing mechanisms of mortality might be implied. Also, in developing management strategies based on risk assessment or for planning clinical trials of therapy after AMI, it would be advantageous if clear-cut follow-up intervals could be established that include most cardiac deaths. Studies following patients 2 to 10 years after AMI have shown that most deaths occur within the first several months,[3–10] whereas beyond the first year the mortality rate stays relatively constant at about 3 to 6% a year.[6–14]

We investigated the appropriateness of an exponential model in 3 geographically distinct populations and considered the possibility that different periods of mortality could be characterized separately. Our goal was to determine whether generalizations can be made (despite variability among populations) concerning time intervals during which the majority of deaths occur in the first year after AMI.

Methods

Populations: Three geographically separate patient populations were used to investigate mortality during the first year after AMI. The population from Copenhagen, Denmark (CPH), consisted of 1,140 patients admitted to the hospital within 24 hours of the onset of symptoms. The diagnosis of AMI was established by at least 2 of the following criteria: (1) a history of characteristic chest pain, (2) electrocardiographic changes indicative of acute myocardial injury with subsequent evolution of a transmural infarction pattern, and (3) characteristic elevations of serum enzymes (creatine kinase, serum glutamic oxalacetic transaminase, or lactic dehydrogenase). Nontransmural infarction was diagnosed by typical S-T segment and T-wave changes accompanied by criteria 1 and 3.[15,16] For uniformity, the populations from Vancouver General Hospital (VANC) with 704 patients and the University of California, San Diego, Medical Center (UCSD) with 346

patients were extracted from their respective data bases to conform to these same criteria. For all 3 populations, patients meeting the foregoing criteria were consecutive.

Tables I and II show the characteristics of the 3 populations. The CPH patients were studied from January 1977 to January 1980, the VANC population over approximately the same period from November 1977 to January 1980. The UCSD population spanned nearly 10 years from August 1968 to June 1979. Follow-up for CPH was 100% and for VANC and UCSD about 93%. Of patients without a 1-year follow-up, 35 of 71 had their final contact during the last 2 months of the year. Patients dying from noncardiac (39) or unknown (21) causes were excluded from further analysis (Table I). All but 1 of the deaths from an unknown cause occurred in CPH where information was obtained from a national registry and the data were incomplete. Cardiac deaths were classified as cardiogenic shock, congestive heart failure, arrhythmia, myocardial rupture, new myocardial infarction, other cardiac (for example, during heart surgery) and sudden death (within 24 hours) presumed cardiac.

Mortality during the first 24 hours was highest for CPH (9%) patients compared with VANC (5%) and UCSD (6%) patients. However, when the period beginning with day 2 after admission through either 15 or 30 days was considered, mortality was more uniform at about 10% for 15 days and 12% for 30 days in each population. During the 364 days after the first day after admission, the mortality was 23% for CPH patients and 21% for both VANC and UCSD patients. Accordingly, we chose to analyze the deaths occurring during this period: CPH had 262 deaths, VANC 146 deaths, and UCSD 71 deaths.

The 3 populations were similar with respect to a number of characteristics recognized as indicative of prognosis (Table II). Heart failure was defined as the presence of rales above the scapula or positive signs of pulmonary venous congestion on chest X-ray during the hospital admission. The percentage of patients dying suddenly was 9% for CPH, 7% for VANC, and 11% for UCSD. A death was classified as sudden if it occurred within a short time (up to 24 hours) from the onset of the episode precipitating it. Documentation concerning the exact timing of events within the 24-hour period was not available. Factors in Table II were not statistically different among the 3 populations.

Other than routine therapy, very little secondary preventative measures were taken. Less than 5% of CPH patients, 18% of VANC patients, and 13% of UCSD patients were discharged on beta blocking drugs. Coronary artery bypass surgery was too rare to be noted. More recent data on patients from VANC (414) and UCSD (334) collected since 1980 indicate that 34% from VANC and 28% from UCSD are now discharged on beta blocking drug therapy. Also, 4% of VANC patients and 15% of UCSD patients have had coronary artery bypass surgery within 1 year after AMI. However, a survival analysis showed minor nonsignificant differences in 1-year survival rates between these new populations and the older data.

TABLE II Population Characteristics

	CPH	VANC	UCSD
Patients (n)	1,140	704	346
Age (yr, mean ± SD)	63 ± 12	65 ± 12	61 ± 13

Congestive heart failure (%)	54	49	49
Sudden cardiac death from admission through 1 year (%)	9	7	11

AMI = acute myocardial infarction; SD = standard deviation; other abbreviations as in Table I.

Statistical methods: Survival curves for the 3 populations were compared with the Mantel-Cox statistic as calculated by the survival function program (P1L) provided in the BMDP Statistical Software Package.[17] This analysis took into account the exact time each patient was followed up to 365 days after admission to the hospital.

All the analyses to be described used only cardiac deaths during the period from day 2 through day 365. Because follow-up was close to 100%, especially during the first 6 months, no provision for lost patients was made in the analyses to be described.

First, a test was made to see if the distribution of deaths was exponential within each population separately and for the combined data base for the entire 364-day period. The statistic used is approximately normally distributed.* Another statistic based on the likelihood ratio was computed to determine a changepoint in time when the distribution of deaths became markedly less dense.* The changepoint determined from the combined data base was used to divide the year into 2 periods (early and late) and the analysis just described was repeated for both periods.

The distribution of deaths expressed as percent of patients still alive at a given point in time was fitted to an exponential curve using the nonlinear regression program (P3R) provided in the BMDP Statistical Software Package.[17] Fits were made for the entire 364-day period and for intervals resulting from the changepoint analysis.

* Details of the derivation and computation of these statistics can be obtained from the authors.

* Changepoint in days from admission. Combined = combined data base; other abbreviations as in Table I.

Results

Survival curves: The survival curves for the 3 populations are shown in Figure 1 and were not different statistically at the $\alpha < 0.05$ level.

Periods of differing mortality distributions: The values of the normally distributed test statistic are shown in Table III. A value of 1.96 for this statistic corresponds to an $\alpha < 0.05$ significance level. Thus, exponentiality for the entire 364-day period after the first day after hospital admission could be ruled out both within each individual population and within the combined population. The statistic for each analysis achieved an actual significance level of $\alpha < 0.0001$.

The changepoint (in days from hospital admission) determined by the likelihood ratio statistic was 24 days for CPH patients, 23 days for VANC patients, 17 days for UCSD patients, and 21 days for the combined data base. Using 21 days to establish 2 separate periods of mortality, the hypothesis of exponentiality could not be rejected for either the early or the late period (Table III).

The mortality within both the early and the late periods was remarkably similar within each population (Table IV). For the combined population, 11.4% of patients died from days 2 to day 21, representing over half (52%) of all deaths during the entire year, whereas during the late period, 10.5% of patients died (48% of deaths).

Separate exponential fits for the distribution of deaths in the early period (days 2 to 21) and in the late period (days 22 to 365) were much tighter than the overall fit obtained using all deaths in the 364-day period. The residual mean square error (an indicator of goodness of fit) summed for both curves in the 2-period analysis was dramatically reduced compared with that resulting from the fit for the entire period, the percent reduction being 76% for CPH patients, 86% for VANC patients, 96% for UCSD patients, and 85% for the combined data base. Figure 2 shows the natural logarithm of the actual survival data for each population. Up to 21 days, only every 10th death is plotted. The straight lines correspond to the fitted exponential curves for the entire 364-day period (single fit) and for the periods through (curve 1) and after (curve 2) day 21. These same data combined over all 3 populations are shown in Figure 2d, but only every 30th point was plotted up to day 21, every 10th point from day 21 through day 90, and every 5th point thereafter. The

actual data in each population appeared to exhibit changepoints at the times calculated from the analysis (Table III).

Table IV gives the time in days by which 50 and 75% of the total deaths during the first year actually occurred in each population and in the combined data base. In the combined data base, 50% of deaths had occurred by day 19 (range days 15 to 21) and 75% had occurred by day 100 (range days 85 to 125).

Discussion

In 3 distinct populations, the 1-year mortality trends after the initial 24-hour period after hospital admission were found to be very similar. For each population, 2 distinct periods with differing exponential distributions of death could be clearly identified. Because the changepoints determined by the likelihood ratio method occurred within a fairly narrow range (17 to 24 days), the changepoint from the analysis of the combined data base (21 days) was used for the remainder of the analyses. None of the results differed substantially when the individual changepoints for each population were used within that population.

Appropriateness of the exponential model: Short-term survival up to 28 days after the onset of AMI has been modeled by a single exponential function for the purpose of studying pathogenic mechanisms and the effects of intensive coronary care.[1,18] One investigator suggested that an exponential survival function was not adequate because the hazard function was not constant but instead was decreasing.[19] The hazard function gives the probability that a patient will die in a short time, that is, 1 day, given that he has survived up to that time. To account for this decreasing force of mortality he chose to model his data with an appropriate Weibull distribution,[20] of which a special case is the exponential distribution. Although the Weibull distribution may have modeled adequately the decreasing force of mortality (in terms of goodness of fit), the decrease in the 3 populations studied appeared to occur rather abruptly, and the use of 2 simple exponentials fits the data well. The existence of a changepoint has clinical implications in that the mode and mechanism of death as well as the set of risk factors for mortality might differ substantially within each period.

The high mortality in CPH patients during the first 24 hours after admission could be due to patients in this population arriving at the hospital very soon after the onset of symptoms and dying shortly after arrival, whereas in the VANC or UCSD population, similar

atients may have died before hospitalization. For CPH atients the time from onset of symptoms to hospitalzation was available in only 813, with 101 of these patients arriving during the 24th hour. Omitting the 24th our group, mean arrival time after onset of symptoms as 4.5 ± 4.2 (standard deviation) hours, with over half f these patients arriving within 3 hours. For VANC atients the mean arrival time was 7.7 ± 5.4 hours and or UCSD patients 10.2 ± 6.3 hours. Neither the VANC or the UCSD population had a group of late arrivals. Omitting deaths occurring during the first 24-hour period after admission reduced the impact on the analysis f early hospital admission (especially for CPH).

If deaths occurring within the first 24 hours of hospital admission had been included, the results for ANC and UCSD patients would have been essentially he same. However, including the 102 such deaths in PH patients caused the hypothesis of exponentiality o be rejected for the early period. The changepoint etermined by the likelihood statistic computed for day through day 21 occurred at the end of day 1, and ortality from day 2 through day 21 did exhibit an exponential distribution. Even though the survival curve f CPH patients did not differ from that of UCSD and ANC patients (Fig. 1), the biphasic exponential fit was ot as good as that in the other 2 populations. For very arly interventions, such as thrombolysis,[21] candidates re generally accepted who arrive at the hospital within few hours of the onset of symptoms, and a separate nalysis of early arriving patients might reveal a omewhat different early survival pattern.[18]

For studying therapeutic interventions applicable to ost patients admitted within 24 hours after the onset f symptoms, our results should be relevant.[22] Such nterventions may seek to influence the acute course, eing instituted at about 24 hours after admission or at he time of hospital discharge to continue 4 to 12 onths. Between 21 and about 100 days, only 25% of irst year deaths will occur, with another 25% occurring hereafter (Table IV).

The identification in our study of 2 separate periods f risk should prove valuable in the design of intervention trials. For early interventions aimed at reducing arly death, a follow-up period of 3 weeks will include ost such deaths. For interventions instituted early, but aimed at reducing mortality well into the posthospital phase, a follow-up period of approximately 3.5 months will encompass 75% of cardiac deaths during the first year. To contain 90% of such deaths, follow-up would have to be well over 7 months, doubling the length and expense of the trial. For trials beginning at the time of hospital discharge it may be necessary to follow patients through the entire year to have a sufficient number of endpoints for analysis, because only about half of deaths during the first year occur after hospital discharge.

Calan® TABLETS
80 mg and 120 mg
(verapamil HCl)

A Freer Life-style For Your Angina Patients

Unsurpassed by propranolol in the treatment of angina

- The efficacy of Calan was unsurpassed by that of propranolol in well-controlled comparative studies involving patients with chronic stable angina.[1-4]
- Calan is very effective in unstable[5] and variant angina,[6] where spasm factors may preclude the use of propranolol.[7]

Low incidence of unwanted effects

- Serious adverse reactions are rare with Calan at recommended doses; the single most common unwanted effect is constipation (6.3%). The therapy continuation rate was 94.5% in clinical studies.[8]
- Unlike beta-blockers, Calan rarely causes extreme fatigue or mental depression.

Benefits even for patients who can't take propranolol

- Calan, unlike propranolol, can be used without added caution in angina patients who also have asthma, chronic obstructive pulmonary disease (COPD), or diabetes.

The only non-nitrate indicated for initial therapy for all types of angina

AWHO

Calan®
(verapamil HCl)
TABLETS
80 mg and 120 mg

A Freer Life-style For Your Angina Patients

▪ Efficacy unsurpassed by propranolol

Calan is effective and, unlike propranolol, is indicated as initial therapy both for stable effort angina and for vasospastic angina.

▪ Therapeutic considerations similar to propranolol

Calan and propranolol have similar cardiovascular contraindications and many of the same cardiovascular adverse reactions (e.g., hypotension, reduction of myocardial contractility, and intensification of AV block).[8,9]

▪ An easy-to-titrate dosage schedule

Initial dosage: 80 mg t.i.d.

Titrate to optimal response: usually 120 mg t.i.d. or q.i.d.

Calan® (verapamil HCl) TABLETS 80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Occasional elevations of liver enzymes have been reported; patients receiving verapamil should have liver enzyme levels monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil. **Precautions:** Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5% of patients, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions, and spotty menstruation. Overall continuation rate was 94.5% in 1,166 patients. **How Supplied:** Calan (verapamil HCl) is supplied in 80-mg and 120-mg sugar-coated tablets.

Validation of Technetium-99m Stannous Pyrophosphate Myocardial Scintigraphy for Diagnosing Acute Myocardial Infarction More Than 48 Hours Old When Serum Creatine Kinase-MB Has Returned to Normal

HAROLD G. OLSON, MD, KENNETH P. LYONS, MD, SAMUEL BUTMAN, MD, and KENNETH M. PITERS, MD

Determination of lactic dehydrogenase (LDH) isoenzymes is the current method of choice for diagnosing acute myocardial infarction (AMI) >48 hours old. However, other causes of enzyme elevation make the availability of an alternate method of diagnosis worthwhile. Accordingly, serial technetium-99m pyrophosphate scintigrams were obtained in 61 patients with transmural AMI and in 46 patients with subendocardial AMI. Imaging was performed in all 107 patients at the time creatine kinase isoenzyme (CK-MB) was present 37 ± 18 hours (range 12 to 72) after the onset of AMI, and at the time CK-MB was absent 106 ± 34 hours (range 48 to 168) after the onset of AMI. At the time CK-MB was absent, the sensitivity using either a regional or a diffuse positive scintigram was 95% (58 of 61 patients) for transmural AMI and 65% (30 of 46 patients) for subendocardial AMI. The sensitivity using a regional positive scintigram was 82% (50 of 61 patients) for transmural AMI and 37% (17 of 46 patients) for subendocardial AMI. The sensitivity using a high-grade regional positive scintigram was 36% (22 of 61 patients) for transmural AMI and 11% (5 of 46 patients) for subendocardial AMI. The specificity was 70% (143 of 204 patients) for either a regional or a diffuse abnormality, 92% (187 of 204 patients) for a regional abnormality, and 100% (204 of 204 patients) for a high-grade regional abnormality. Thus, pyrophosphate scintigraphy is useful in confirming the diagnosis of AMI, particularly transmural, >48 hours old and when CK-MB has returned to normal. A positive scintigram with a high-grade regional abnormality is specific for a recent AMI and may be contributory in establishing the diagnoses when LDH isoenzymes are inconclusive.

Since Bonte's pioneering work in 1974, technetium-99m stannous pyrophosphate myocardial scintigraphy has been widely used in diagnosing acute myocardial infarction (AMI).[1–8] If myocardial scintigrams are obtained between 24 and 72 hours after the onset of symptoms of AMI, >95% of patients with transmural AMI and from 38 to 92% of patients with subendocardial AMI will be detected.[1–9]

However, most patients with AMI can be diagnosed within 24 to 72 hours by serial electrocardiography and serum enzyme determinations at the time imaging with pyrophosphate is optimal. Pyrophosphate imaging in these cases would be unnecessary. Despite this limitation, pyrophosphate imaging has been useful in diagnosing perioperative AMI, localizing AMI (particularly right ventricular AMI), assessing the size of anterior transmural AMI, and providing prognostic information in patients during and after AMI, and in patients with unstable angina pectoris.[10–16]

It is frequently stated and commonly believed that the major role of pyrophosphate scintigraphy is diagnosing AMI in patients presenting >48 hours after onset of AMI when creatine kinase isoenzyme (CK-MB) has returned to normal.[17] In a limited number of patients studied by Parkey et al,[2] this would seem to be true although serial enzymes were not reported. Accordingly we performed a prospective, controlled study to determine the reliability of diagnosing AMI by technetium-99m pyrophosphate scintigraphy when serum CK-MB returned to normal. Serial pyrophosphate scintigrams

nd enzymes were obtained in patients during the first days after the onset of AMI when serum CK-MB was resent, during 3 to 7 days after the onset of AMI when erum CK-MB was absent, and at hospital discharge.

Methods

From January 1980 to February 1981, 175 consecutive pa-ients admitted to the coronary care unit met our criteria for MI: (1) typical history of chest pain, (2) classic evolutionary lectrocardiographic changes, and (3) the presence of serum K-MB. AMI was localized by standard electrocardiographic riteria. Transmural AMI was defined by the presence on erial electrocardiograms of new Q waves with a duration of .04 second or more and amplitude >25% of the R wave in the ame lead, accompanied by evolutionary changes in the S-T egment and T wave. Subendocardial AMI was defined by the resence on serial electrocardiograms of new S-T segment hanges with or without T-wave abnormalities that persisted 24 hours.

Of the 175 patients, 68 (39%) were excluded from the study or the following reasons: (1) death within 96 hours after ospital admission (25 patients), (2) transthoracic cardio-ersion during coronary care unit stay (11 patients), or (3) ncomplete serial pyrophosphate studies. The patient did not ave a scintigram when serum CK-MB was present or when erum CK-MB was absent, or both, because of either clinical nstability or scintillation camera or radionuclide unavail-bility (29 patients), and refusal to participate in the study 3 patients).

The remaining 107 patients (61%) formed the patient opulation for the study. There were 106 men and 1 woman ith a mean age of 60.4 years (range 40 to 87). Sixty-one pa-ents had acute transmural AMI and 46 patients had acute ubendocardial AMI. Of the 61 patients with acute transmural MI, the AMI was anterior in 26 patients, inferior in 31, and nteral in 4. Of the 107 patients, 59 were Killip class I, 43 were illip class II, and 5 patients were Killip class III. Of the 107 atients, 39 (36%) had a history of previous AMI.

During the first 24 hours after hospital admission, all 107 atients had blood drawn for serum CK and CK-MB analysis very 8 hours, then daily for 7 days. In addition, all 107 pa-ents had blood drawn daily for serum LDH and hydrooxy-utyric dehydrogenase (HBD) analysis for 7 days after ad-nission. Serum CK-MB was determined by the cellulose ac-tate electrophoretic method. Significant CK-MB isoenzyme as reported present if more than a trace was detected by lectrophoresis.

After informed written consent, pyrophosphate imaging was erformed in all 107 patients at the time serum CK-MB was etected 37 ± 18 hours (range 12 to 72) after the onset of in-rction and at the time serum CK-MB was no longer detected 06 ± 34 hours (range 48 to 168) after the onset of AMI. Of the 07 patients, 97 (91%) had a follow-up scintigram before ospital discharge 21 ± 10 days after hospital admission. iming for pyrophosphate imaging was based on the results serum CK-MB analysis and scintillation camera and ra-onuclide availability. Imaging was performed within 3 hours CK-MB determinations. The initial scintigram was per-rmed within 72 hours of the onset of symptoms when serum K-MB was detected. It was attempted to obtain the second intigram on the first day in which CK-MB was no longer etectable. In some patients, the second scintigram was ob-ined 2 to 4 days after CK-MB had returned and remained ndetectable. None of the 107 patients had an episode of chest ain >15 minutes within 12 hours of the second scintigram. ecurrent AMI was excluded on clinical and electrocardio-aphic criteria before the follow-up scintigram.

Myocardial scintigrams were obtained 3 to 4 hours after the injection of 20 mCi of technetium-99m pyrophosphate, which contained <0.15 mg of tin. Chromatography was performed before each study to document the binding efficiency of the radiopharmaceutical. Myocardial scintigrams were recorded using a 37 PM tube, 11-inch standard field of view camera (420 Ohio Nuclear Portable or Pho Gamma V) fitted with a high resolution collimator.

Imaging was performed in anterior, 45° left anterior oblique, and left lateral views. Each view contained 400,000 counts with the 20% window and the photo-peak centered on 140 KeV. Serial studies on individual patients were performed with the same camera. Delayed imaging was performed at 4 hours in all patients suspected of having persistent blood pool activity.

Myocardial scintigrams were interpreted and graded in the following manner. The intensity of radioactivity in the area of the left ventricle was graded from 0 to 3+. Zero activity indicated no activity. An intensity of 1+ was assigned for activity less than that of the rib, 2+ for activity equal to or greater than rib activity, and 3+ for activity equal to or greater than sternal activity. A scintigram of 2+ or greater was considered positive. Our grading system differs from that proposed by Parkey et al[2] and Willerson et al.[3] A 2+ scintigram in our grading system corresponds to a 3+ scintigram in their system. This distinction is important because some investigators have considered a 2+ scintigram, according to the Parkey classification, as equivocal, but not a diagnostically positive scintigram.[18]

Myocardial scintigrams were also graded according to the distribution of activity. Regional uptake was assigned when activity could be localized to a discrete region of the left ventricle. Poorly localized activity was defined as diffuse uptake.

In comparing follow-up scintigrams with those obtained when serum CK-MB was detected, the following grading system was used. Follow-up scintigrams were considered improved if there was a decrease in the intensity of activity or if there was a change in the activity pattern from regional to diffuse. Follow-up scintigrams were considered worse if there was an increase in intensity of activity or a new regional abnormality pattern.

One hundred seven consecutive patients with unstable angina admitted to the coronary care unit during January 1980 to February 1981 who had a myocardial scintigram within 3 days after admission to the coronary care unit were the control patients. Unstable angina pectoris was defined as angina at rest lasting >15 minutes and no evidence of acute myocardial infarction after a 3-day observation period, as determined by serial electrocardiograms and serum enzyme determinations. None of the patients had new persistent S-T or T-wave changes or new Q waves on their electrocardiograms or an abnormal increase in serum CK, CK-MB isoenzyme, or serum HBD. These patients included 106 men and 1 woman, mean age 59.6 ± 10 years (range 30 to 82).

The myocardial scintigrams were interpreted by 2 experienced observers without knowledge of the patient's diagnosis or the results of enzyme determinations. When there was any disagreement in the interpretation of a scintigram, the lower grade was assigned. There was complete agreement between the observers in 90% of the scintigrams interpreted.

The data are presented as the means ±1 standard deviation. Sensitivity (%) was defined as the number of true-positive scintigrams divided by the number of true-positive plus false-negative results multiplied by 100. Specificity (%) was defined as the number of true-negative scintigrams divided by the number of true-negative plus false-positive results multiplied by 100. Chi-square analysis was used to test for significant differences.

TABLE I Characteristics of Technetium-99m Pyrophosphate Myocardial Scintigrams Obtained in Patients During Acute Myocardial Infarction, at Follow-up, and in the Control Group

		Positive Scintigrams				Negative Scintigrams	
	Patients	R_3	R_2	D_3	D_2	D_1	0
Acute phase: CK-MB present (12 to 72 hours after AMI)							
All patients with AMI	107	26	41	1	19	12	8
Transmural AMI	61	21	28	1	7	3	1
Anterior wall	26	12	11	0	3	0	0
Inferior wall	31	6	16	1	4	3	1
Lateral wall	4	3	1	0	0	0	0
Subendocardial AMI	46	5	13	0	12	9	7
Acute phase: CK-MB absent (48 to 168 hours after AMI)							
All patients with AMI	107	27	40	0	21	6	13
Transmural AMI	61	22	28	0	8	1	2
Anterior wall	26	10	13	0	1	1	1
Inferior wall	31	11	12	0	7	0	1
Lateral wall	4	1	3	0	0	0	0
Subendocardial AMI	46	5	12	0	13	5	11
Follow-up 21 ± 10 days after AMI							
All patients with AMI	97	0	10	0	27	39	21
Transmural AMI	54	0	7	0	11	25	11
Anterior wall	25	0	2	0	7	13	3
Inferior wall	25	0	4	0	3	11	7
Lateral wall	4	0	1	0	1	1	1
Subendocardial AMI	43	0	3	0	16	14	10
Controls	107	0	7	0	17	34	49

AMI = acute myocardial infarction; D_1 = diffuse 1+ activity; D_2 = diffuse 2+ activity; D_3 = diffuse 3+ activity; 0 = no activity; R_2 = regional 2+ activity; R_3 = regional 3+ activity.

Results

Scintigraphic findings at the time serum CK-MB was present (12 to 72 hours) after AMI (Table I): Fifty-seven of the 61 patients with transmural AMI (93%) had positive scintigrams with either a regional or a diffuse abnormality. Forty-nine of 61 patients with transmural AMI (80%) had positive scintigrams with a regional abnormality (Fig. 1).

Thirty of the 46 patients with subendocardial AMI (65%) had positive scintigrams with a regional or a diffuse abnormality. Of the 46 patients with subendocardial AMI, 18 (39%) had positive images with a regional abnormality.

At scintigraphy, the total serum CK was 1,160 ± 751 units/liter (range 243 to 4,120) for patients with transmural AMI and 488 ± 316 units/liter (range 194 to 1,201) for patients with subendocardial AMI. The normal range for total serum CK for our laboratory is 35 to 232 units/liter. Of the 46 patients with subendocardial AMI, 3 (6%) had total serum CK in the normal range when serum CK-MB was detected.

Scintigraphic findings at the time serum CK-MB was absent (48 to 168 hours) after AMI (Tables I and II): Fifty-eight of the 61 patients with transmural AMI (95%) had positive scintigrams with either a regional or a diffuse abnormality. Fifty of 61 patients with transmural AMI (82%) had positive scintigrams with a regional abnormality (Fig. 1).

Thirty of the 46 patients with subendocardial AMI (65%) had positive scintigrams with either a regional or a diffuse abnormality. Of the 46 patients with subendocardial AMI, 17 (37%) had a positive study with a regional abnormality.

At scintigraphy, the total serum CK was 150 ± 51.1 units/liter (range 55 to 292) for patients with transmural

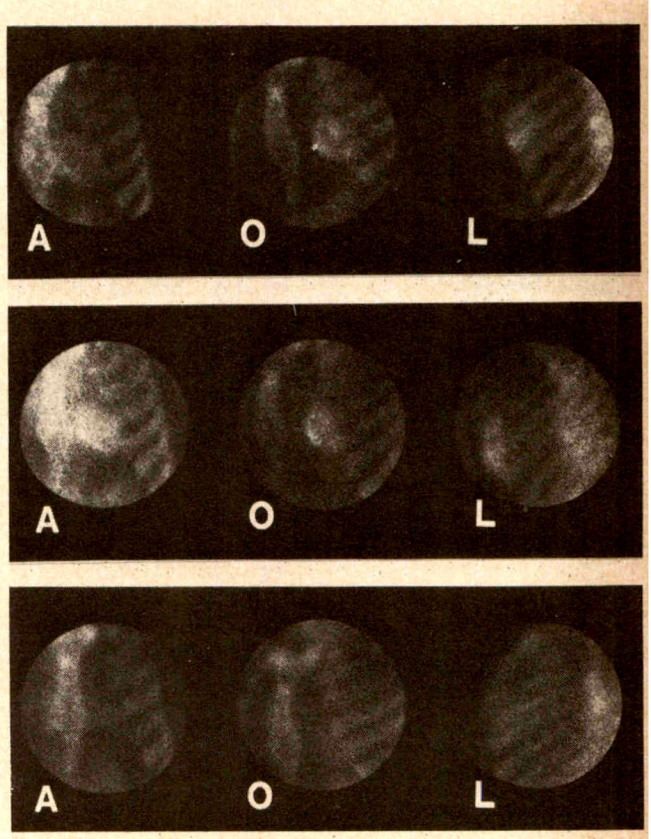

FIGURE 1. Upper panel, a 2+ regional abnormality (positive scintigram) in a patient with anterior wall acute myocardial infarction (AMI) 50 hours after the onset of AMI when serum CK-MB was present. **Middle panel,** a 3+ regional abnormality (positive scintigram) in the same patient 78 hours after the onset of AMI when serum CK-MB was absent. **Lower panel,** a negative scintigram at follow-up 15 days after the onset of AMI. A = anterior view; L = left lateral view; O = 45° left anterior oblique view.

ABLE II Correlation Between Scintigraphic Findings and Serum HBD in the 107 Patients 48 to 168 Hours After Acute Myocardial Infarction at the Time Serum CK-MB Was Absent

	Positive Scintigram					
	Regional or Diffuse Abnormality		Regional Abnormality		Elevated Serum HBD	
	n	%	n	%	n	%
ransmural AMI (61 patients)	58	95*,†	50	82*	55	90‡
ubendocardial AMI (46 patients)	30	65§	17	37	33	72¶
ll patients with AMI (107 patients)	88	82‡,‖	67	62	88	82‖

* p <0.001 when compared with subendocardial AMI.
† p <0.05 when compared with transmural AMI with a regional abnormality.
‡ p <0.05 when compared with subendocardial AMI.
§ p <0.01 when compared with subendocardial AMI with a regional abnormality.
¶ p <0.01 when compared with patients with subendocardial AMI with a positive scintigram with a regional abnormality.
‖ p <0.01 when compared with all patients with AMI with a regional abnormality.
AMI = acute myocardial infarction; HBD = hydrooxybutyric dehydrogenase.

MI and 143 ± 47.4 units/liter (range 36 to 269) for atients with subendocardial AMI. Six percent of pa- ients with transmural AMI (4 patients) and 6% of pa- ients with subendocardial AMI (3 patients) had slightly levated serum CK levels when CK-MB was unde- ected.

Figures 2 to 5 show the prevalence of positive scinti- rams in patients with transmural and subendocardial MI at the time serum CK-MB was present, at the time erum CK-MB was absent, and at follow-up.

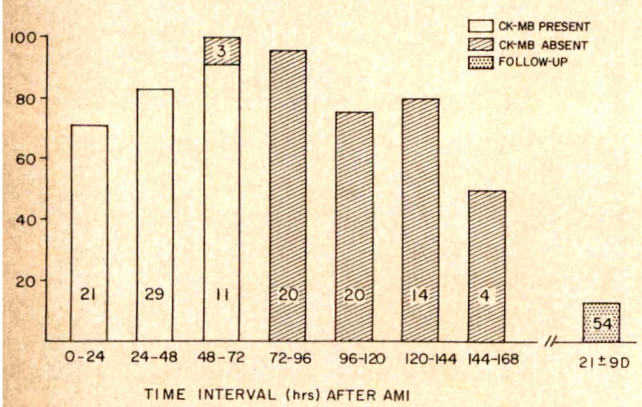
The peak incidence of positive scintigrams with a egional abnormality for transmural AMI occurred etween 48 and 96 hours after the onset of AMI. Ninety o 100% of patients with transmural AMI had positive tudies with a diffuse or regional pattern 12 to 120 hours fter the onset of AMI. The incidence of positive scin- igrams in patients with subendocardial AMI was ariable during the week after AMI.

The correlation between scintigraphic findings and erum HBD at the time serum CK-MB was absent is summarized in Table II. If the criterion for a positive scintigram was a regional abnormality, serum HBD was more sensitive than the scintigram for diagnosing subendocardial AMI when CK-MB was absent.

Of the 4 patients with inferior AMI with negative scintigrams when serum CK-MB was present, 3 had positive scintigrams when CK-MB was absent (Fig. 6). Similarly, 4 of the 16 patients with subendocardial AMI (25%) with negative scintigrams when CK-MB was present had positive scintigrams when CK-MB was absent. Thus, serial scintigraphy was able to diagnose AMI in 60 of 61 patients with transmural AMI (98%) and AMI in 34 of 46 patients with subendocardial AMI (74%).

Scintigraphic findings at follow-up (Table I): Of the 54 patients with transmural AMI who had follow-up scintigraphy, 7 (13%) had positive scintigrams with a 2+ regional abnormality at follow-up. Eighteen of the 54 patients (33%) had positive scintigrams with either a regional or a diffuse abnormality.

Of the 43 patients with subendocardial AMI, 3 (7%) had positive scintigrams with a 2+ regional abnormality



IGURE 2. Prevalence of positive scintigrams with a regional pattern patients with transmural acute myocardial infarction (AMI) evaluated ring the first week after the onset of AMI. The number of patients udied at each time interval is indicated in the bars. All intervals are gnificantly different compared with follow-up interval, p <0.001, cept interval 144 to 168 hours which is significantly different at p 0.05. Interval 72 to 96 hours is significantly different compared with terval 0 to 24 hours and interval 144 to 168 hours, p <0.05.

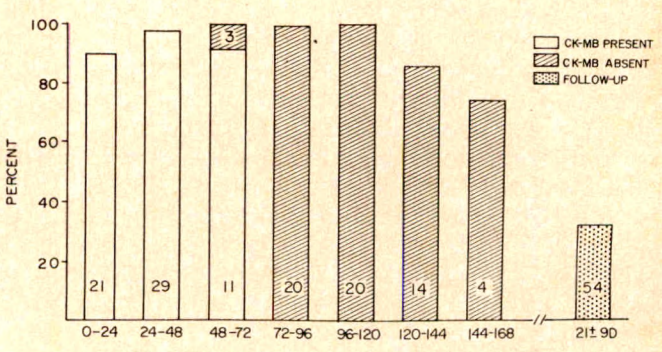


FIGURE 3. Prevalence of positive scintigrams with a regional or a diffuse pattern in patients with transmural acute myocardial infarction (AMI) evaluated during the first week after the onset of AMI. The number of patients studied at each time interval is indicated in the bars. All intervals are significantly different compared with follow-up interval, p <0.001, except interval 144 to 168 hours which is not significant. D = days; hrs = hours.

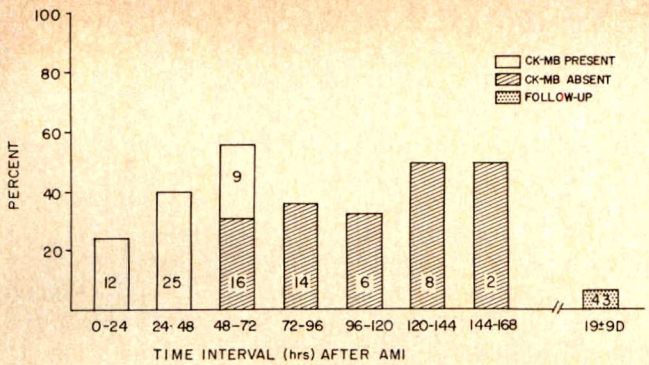

FIGURE 4. Prevalence of positive scintigrams with a regional pattern in patients with subendocardial acute myocardial infarction (AMI) evaluated during the first week after the onset of AMI. The number of patients studied at each time interval is indicated in the bars. Intervals: 48 to 72 hours, $p < 0.001$; 24 to 48 hours, 72 to 96 hours, 120 to 144 hours, $p < 0.01$; and 96 to 120 hours, 144 to 168 hours, $p < 0.05$, are significantly different compared with follow-up interval. Interval 0 to 24 hours is not significantly different compared with follow-up interval. D = days; hrs = hours.

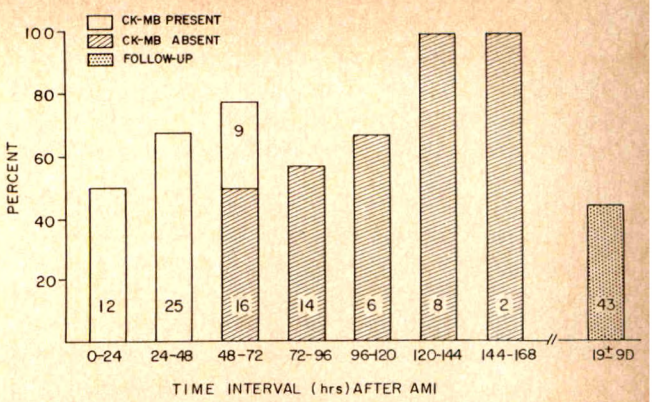

FIGURE 5. Prevalence of positive scintigrams with a regional or a diffuse pattern in subendocardial patients with acute myocardial infarction (AMI) evaluated during the first week after the onset of AMI. The number of patients studied at each time interval is indicated in the bars. Interval 120 to 144 hours is the only interval significantly different compared with the follow-up interval, $p < 0.01$. Interval 120 to 144 hours was significantly different compared with interval 0 to 24 hours and interval 72 to 96 hours, $p < 0.05$. D = days; hrs = hours.

at follow-up. Nineteen of these 43 patients (44%) had positive images with a regional or a diffuse abnormality at follow-up. None of the patients with transmural or subendocardial AMI had a positive scintigram with a 3+ abnormality.

Of the 30 patients with a history of previous AMI and a positive scintigram when CK-MB was present, 25 (83%) had an improved or negative scintigram at follow-up.

Of the 97 patients who had follow-up scintigraphy, 80 (82%) had positive scintigrams with a regional or a diffuse abnormality when serum CK-MB was absent. In comparing the scintigrams obtained at the time serum CK-MB was absent with those at follow-up, it is noteworthy that in 81% of cases, the scintigraphic abnormalities were either improved or negative (Fig. 1).

Control subjects (Table I): Of the 107 control patients, 7 (7%) had positive scintigrams with a 2+ regional abnormality. Twenty-four patients (22%) had positive scintigrams with a regional or a diffuse abnormality. None of the control patients had a 3+ regional abnormality.

The specificity of pyrophosphate scintigraphy for diagnosing AMI in this study was determined by combining the results of scintigraphy in the 97 patients with AMI at follow-up with the results obtained in the 107 control patients. The specificity was 70% (143 of 204 patients) for a 2+ abnormality (regional or diffuse), 92% (187 of 204 patients) for a 2+ regional abnormality, and 100% (204 of 204 patients) for a 3+ regional abnormality.

Discussion

Recent studies indicate that serum CK-MB isoenzyme determination is the most sensitive and specific method for diagnosing AMI.[9,19] However, it is of limited value for AMI occurring several days before hospital admission. For AMI >48 hours old, determination of serum LDH, LDH isoenzymes, or HBD activity is required to diagnose AMI.[20,21]

Separation and quantification of the isoenzymes of LDH increase specificity and accuracy for diagnosing AMI.[22] Vasudevan et al[21] showed that using the criterion of a reversal of LDH_1:LDH_2 >0.77 improved the sensitivity and specificity of LDH isoenzymes for diagnosing AMI. However, the sensitivity and specificity of the reversal of LDH_1:LDH_2 ratio for diagnosing AMI >48 hours old has not been completely evaluated. LDH_1 and LDH_2 isoenzymes are present in the kidneys, red blood cells, and brain and, to a lesser extent, in the lung.[22] Both hemolysis, such as occurs during simple withdrawal and handling of blood specimens, and renal disease can result in a false-positive LDH_1:LDH_2 pat-

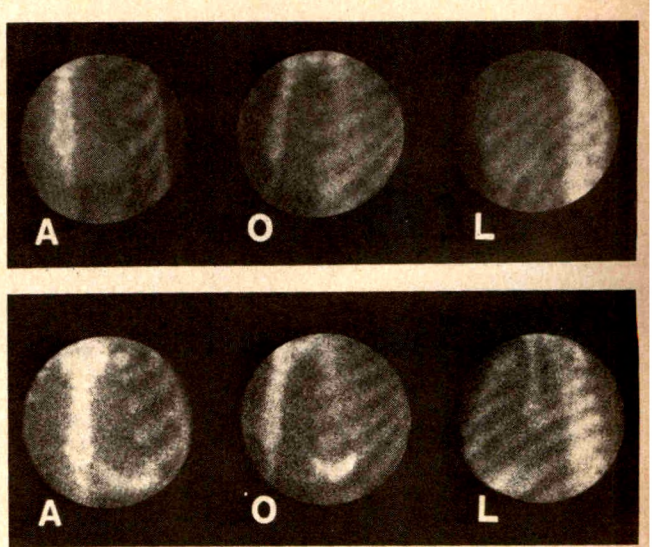

FIGURE 6. Upper panel, a diffuse 1+ abnormality (negative scintigram) in a patient with acute myocardial infarction (AMI) of the inferior wall 20 hours after the onset of AMI when serum CK-MB was present. **Lower panel,** a 3+ regional abnormality in the same patient 80 hours after the onset of AMI when serum CK-MB was absent. A = anterior view; L = left lateral view; O = 45° left anterior oblique view.

tern.[20] Moreover, a reversed ratio of LDH_1:LDH_2 is commonly found in young women, particularly during pregnancy.[23] Because of these problems with the current enzymatic methods, an alternative approach for diagnosing AMI that is >48 hours old would be worthwhile.

The major finding of the present study is that pyrophosphate myocardial scintigraphy is useful in diagnosing AMI, especially transmural AMI, during the first week after the onset of infarction when serum CK-MB is no longer detectable. Of the patients with transmural AMI, 95% had positive scintigrams with either a regional or a diffuse abnormality and 82% had positive scintigrams with a regional abnormality 3 to 7 days after the onset of AMI when serum CK-MB was no longer detectable. However, pyrophosphate myocardial scintigraphy is of limited value in diagnosing a 3- to 7-day old subendocardial AMI. Of patients with subendocardial AMI, 65% had positive scintigrams with a regional or diffuse abnormality and 37% had positive scintigrams with a regional abnormality when serum CK-MB was absent.

Previous animal and human studies have shown that pyrophosphate scintigraphy can detect myocardial necrosis within 12 hours after the onset of symptoms of AMI. Serial imaging indicates that the scintigrams become increasingly more positive 48 to 72 hours after the onset of AMI. There is then a gradual decrease in radioactivity in the infarcted area and the myocardial scintigram is usually negative by 2 weeks after the onset of AMI.[2,3,8,24] Myocardial scintigrams remain persistently positive in a minority of patients (usually a low-grade, diffuse abnormality) 3 to 6 months after AMI.[14,15] The suggested mechanisms for persistently positive scintigrams include left ventricular aneurysm and slow, on-going necrosis.[15,25]

The data from the present study support these experimental studies and human observations. The peak incidence of positive scintigrams with a regional abnormality occurred between 48 and 96 hours after the onset of AMI in patients with acute transmural AMI and between 24 and 72 hours after the onset of AMI in patients with subendocardial AMI. The later time for the appearance of a regional abnormality during transmural AMI may be due to the fact that a transmural AMI is more likely to be an occlusive AMI with later reperfusion.[26] Long et al[27] showed that during experimental AMI, early appearance of pyrophosphate uptake suggested a reperfusion AMI compared with later uptake in occlusive AMI.

The present study was not designed to compare pyrophosphate scintigraphy with serum enzymes such as LDH isoenzymes and HBD activity in diagnosing infarction that is several days old when serum CK-MB is no longer elevated. The sensitivity with either test was similar (pyrophosphate scintigraphy 82% and serum HBD activity 82%).

In our study, hospitalized patients with unstable angina were included in our control population because these patients would be most likely to have scintigraphy. Previous studies indicate that approximately one third of patients with unstable angina have abnormal scintigrams.[16,28] Histologic studies support the occurrence of myocardial necrosis associated with such abnormal scintigrams.[15] Accordingly, the specificity data refer to the routine clinical documentation of AMI by electrocardiogram and serum CK-MB. Specificity of pyrophosphate scintigraphy for diagnosing AMI is dependent on the nature of the patient population and the timing and sensitivity of the CK-MB assay.

In our study, a regional abnormality on pyrophosphate scintigraphy was specific for a recent AMI (92%). The specificity of a high-grade regional abnormality (localized activity greater than or equal to that in the sternum) was 100%. Whether pyrophosphate scintigraphy is more specific for diagnosing AMI when recent CK-MB is absent as compared with LDH isoenzymes will require further study. Pyrophosphate imaging may be helpful in confirming the diagnosis of recent AMI when LDH isoenzymes are equivocal or in clinical situations such as acute hemolysis when LDH isoenzymes are unreliable.

Evaluation of Serial QRS Changes During Acute Inferior Myocardial Infarction Using a QRS Scoring System

CHRISTINE I. ANDERSON, BA, DAVID G. HARRISON, MD, NANCY C. STACK, BA, NANCY B. HINDMAN, BA, RAYMOND E. IDEKER, MD, PhD, SEBASTIAN T. PALMERI, MD, RONALD H. SELVESTER, MD, and GALEN S. WAGNER, MD

The evolution of changes in the QRS complex during the initial 3 days after the onset of an initial inferior myocardial infarction (MI) was studied in 82 consecutive patients. Each patient's standard 12-lead electrocardiogram was assigned points (a QRS score) according to the absolute duration of the Q and R waves and the amplitude ratios of R-to-Q and R-to-S waves. This QRS score has been demonstrated to correlate (r = 0.74) with the anatomic extent of single inferior MI. By this sytem, 43 patients (53% of the study group) had an initial electrocardiogram that registered a score of 0 and developed QRS points only after admission. The QRS scores of 18 additional patients (22% of the study group) changed after admission. Forty-nine score changes were noted on Day 2 and 18 on Day 3. All of these changes resulted in an increased QRS score.

Alteration of the QRS complex during initial inferior MI evolves over 2 to 3 days in many patients. There is a distinct pattern to this evolution, which results in sequential increases in a QRS score based upon electrocardiographic indicators of the extent of myocardial necrosis. This QRS scoring system might be applied to evaluate clinically interventions aimed at limiting the extent of necrosis in patients with initial acute inferior MI.

The effects of myocardial infarction (MI) on the scalar electrocardiogram have been recognized almost since the advent of electrocardiography.[1,2] In the QRS complex, R waves diminish and Q waves develop.[3–6] The temporal course of these changes has not been completely elucidated. In *Heart Disease*, a 1982 textbook of cardiovascular medicine,[7] QRS evolution is discussed only in reference to a hand-drawn diagram originally published by Lepeschkin in 1951.[8] This diagram suggests that acute QRS changes are limited to the first day after the onset of MI. Other reports have described changes in the QRS complex occurring over several days.[9,10] The present study examines the incidence, timing, and quantitative appearance of QRS changes during the first 3 days after the onset of initial, acute, inferior MI.

A recently developed[11,12] and simplified[13] QRS scoring system quantifies the QRS changes which occur as a result of MI. In the absence of other factors affecting the QRS complex, the magnitude of the QRS score correlates well with the size of both anterior[14] and inferior[15] MI determined at autopsy. It also correlates with decreases in left ventricular ejection fraction that result from MI.[16] The electrocardiograms of patients included in the present study were evaluated according to this QRS scoring system.

Methods

Patient population: During an 8-year period, 271 patients with acute inferior MI were admitted to the Duke University Medical Center Coronary Care Unit. Twelve-lead electrocardiograms were performed in these patients on admission and at least once daily for the first 3 hospital days. Serum enzymes, including creatine kinase (CK) and the nearly cardiac-specific isoenzyme CK-MB, were measured at varying intervals in all patients.

The 82 patients included in this study met the following criteria: (1) no MI by history or electrocardiogram, (2) acute

TABLE I QRS Scoring System

Category	Lead	Duration (ms)	Amplitude Ratio (ms)	Maximum Points
Criterion for IMI required for inclusion in study	aVF	Q ≥ 30 (1)		1
Additional criteria for IMI	II	Q ≥ 40 (2)		
		Q ≥ 30 (1)		2
	aVF	Q ≥ 50 (3)	R/Q ≤ 1 (2)	
		Q ≥ 40 (2)	R/Q ≤ 2 (1)	4
Criteria for posterior involvement	V_1	R ≥ 50 (2)		
		R ≥ 40 (1)	R/S ≥ 1 (1)	3
	V_2	R ≥ 60 (2)		
		R ≥ 50 (1)	R/S ≥ 1.5 (1)	3
Criteria for apical involvement	V_5	Q ≥ 30 (1)	R/Q or R/S ≤ 1 (2)	
			R/Q or R/S ≤ 2 (1)	3
	V_6	Q ≥ 30 (1)	R/Q or R/S ≤ 1 (2)	
			R/Q or R/S ≤ 3 (1)	3
Criteria for anterior and lateral involvement used for exclusion from this study	I	Q ≥ 30 (1)	R/Q ≤ 1 (1)	2
	aVL	Q ≥ 30 (1)	R/Q ≤ 1 (1)	2
	V_1	Any Q (1)		1
	V_2	Any Q or R ≤ 10 (1)		1
	V_3	Any Q or R ≤ 20 (1)		1
	V_4	Q ≥ 20 (1)	R/Q or R/S ≤ 0.5 (2)	
			R/Q or R/S ≤ 1 (1)	3

IMI = inferior myocardial infarction.

infarction as indicated by elevation of S-T segments and the appearance of CK-MB in the serum sample, (3) definite inferior infarction as marked by the appearance of a Q wave ≥30 ms in lead aVF, (4) the absence of a concurrent anterior or lateral infarct (Table I), and (5) records of daily, scorable electrocardiograms for at least the first 3 hospital days. Electrocardiographic scorability required the absence of left and right ventricular hypertrophy, ventricular tachycardia, paced rhythms, left or right bundle branch block, and left anterior or posterior fascicular block.

Electrocardiogram and enzyme analysis: Electrocardiograms were recorded in the standard manner at 25 mm/s paper speed and 10 mm/mV amplitude. QRS complexes were measured with calipers and scored according to the system developed by Selvester et al[11,12] and simplified[13] and evaluated[14,15] by Wagner, Ideker, and their co-workers. Points were assigned according to the duration of Q and R waves and the amplitude ratios of R-to-Q or R-to-S waves (Table I). The amplitude ratios of R-to-Q waves were considered in a given lead only when a Q-wave duration criterion was satisfied in that lead.

QRS points achieved in leads II and aVF were attributed to inferior infarction; lead III is not considered in the QRS scoring system. When R-wave duration and R/S amplitude ratios were sufficiently increased to be assigned points in leads V_1, V_2, or both, the adjacent posterior myocardium was considered to be involved in the infarct. Adjacent apical involvement was identified by points in leads V_5 and V_6.

Although multiple electrocardiograms were performed in a single day on some patients, only 1 per day was consistently available in the population of this study. For that reason, only 1 QRS score per day could be applied in data analysis. When more than one electrocardiogram was available, the admission QRS score was used for Day 1 and the highest daily score was used for Days 2 and 3.

CK determinations were performed by the method of Rosalki[17] using the modified reagent substrate prepared by Eskalab. CK isoenzymes were identified using the Corning method with agarose electrophoresis.

Definitions: A *QRS change* refers to a score increase or decrease of ≥2 points compared with a previous observation. Minor fluctuations in R-wave and Q-wave dimensions resulted in frequent, transient, 1-point variations which were attributed to uncontrolled variables such as respiration, abdominal distention, and patient position. When sequential 1-point variations accrued to 2 points, thereby meeting the criterion for QRS change, the day on which the second point was observed was arbitrarily considered to be the day of QRS change.

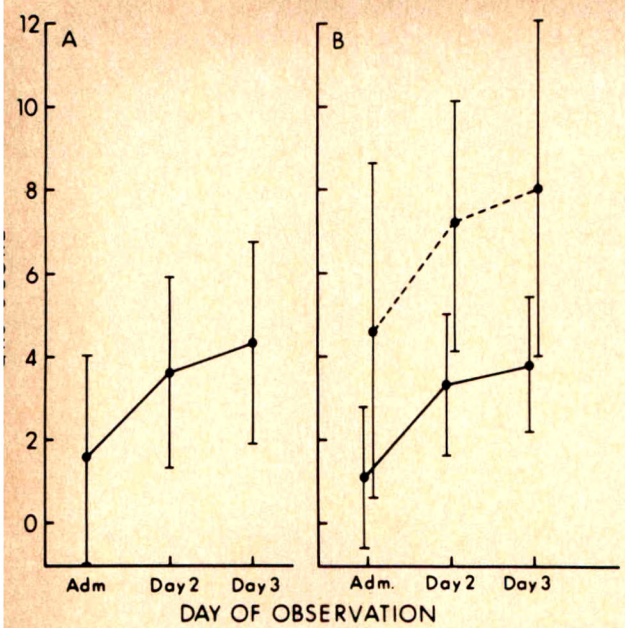
Day 1 began at the time of admission if CK-MB appeared in the serum sample within 24 hours. When no CK-MB appeared, the episode prompting admission was considered to have been unstable angina and Day 1 of the acute infarct was defined as beginning 12 hours before the first appearance of CK-MB. Day 1 always ended at 7:00 A.M. and every day thereafter lasted 24 hours.

Results

Eighty-two patients met the criteria for inclusion in this study, 72 of them with the QRS characteristics of inferior infarction alone. These patients' QRS changes occurred only in leads II and aVF, and they consisted of abnormal Q-wave durations and Q- to R-wave amplitude ratios (Table I). In 10 patients, these signs of inferior infarction were accompanied by changes in the chest leads, which indicated involvement of adjacent apical (1 patient), posterior (4 patients), or both apical and posterior areas of the myocardium (5 patients) (Table I).

Figure 1A illustrates the mean QRS scores observed during the first 3 hospital days. The 82 patients in the study had an average of 1.6 QRS points at admission, 3.8 points on Day 2, and 4.3 points on Day 3. Figure 1B provides the same information with the study group divided according to infarct location. The 10 patients with apical or posterior involvement or both had higher average QRS scores than those with only localized inferior infarcts (difference approximately 4 QRS points).

QRS score changes during the first 3 hospital days are summarized in Table II. Forty-three patients (53% of



GURE 1. Daily mean QRS scores (± 1 standard deviation). **A,** all atients in the study (n = 82). **B,** patients with localized inferior infarction **olid lines;** n = 72) compared with patients with apical or posterior volvement, or both, with inferior infarction (**dashed lines;** n = 10).

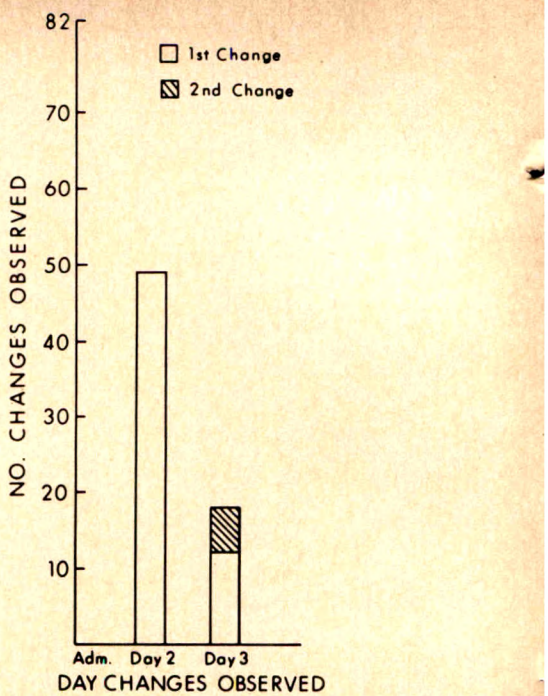


FIGURE 2. Days on which QRS changes were observed. Changes in relation to the admission QRS score are outlined; changes from the Day 2 score are shaded.

ıe study population) were admitted with a QRS score f 0. In 39 of these patients, the QRS score changed once fter admission; in 4 it changed twice. The other 39 atients in the study were admitted with ≥1 QRS oints. In 21 of them the QRS score did not change, in 3 it changed once, and in 2 it changed twice during the rst 3 hospital days. All 61 changes during this period sulted in increased QRS scores.

As Table III indicates, patients with adjacent apical r posterior infarct involvement, or both, were more likely than those with localized inferior infarcts to have been admitted with a QRS score >0. The number of patients in the apical or posterior groups, or both, was too small for consideration of statistical significance. The incidences of 0, 1, and 2 score changes were similar in the 2 groups of patients.

The timing of QRS score changes is summarized in Figure 2. The electrocardiograms of 49 patients indicated a change in QRS score between admission and Day 2. By Day 3, 12 more patients' scores had changed from admission. Six of the patients whose QRS scores had changed by Day 2, changed a second time by Day 3.

Electrocardiograms were available after Day 3 in a diminishing number of patients. Table IV shows that the incidence of change in QRS scores decreased markedly after Day 3, but a few changes in QRS scores were observed as late as Day 7. The score increases

ABLE II QRS Score Changes During the First 3 Hospital Days

noted after Day 3 all followed a period of 2 to 6 days without a score change. One patient's QRS score decreased on Day 6 from a higher score observed on Day 2.

Discussion

This study demonstrates that (1) changes in the QRS complex after the onset of MI often evolve over a longer period than that previously described, and (2) these changes follow a pattern. More than half of the patients studied were admitted before the development of abnormal Q waves. After admission, QRS changes were observed on Day 2 or 3 in most patients. All of the 61 observed changes during the first 3 days and 4 of the 5 late changes yielded increased QRS scores.

The appearance of the QRS complex after an infarct varies with the location,[18] the transmural depth,[8] and the subendocardial area[19] of the necrotic myocardium. The QRS scoring system devised by Selvester et al[11,12] and simplified by Wagner et al[13] quantifies the effects of these variables on the electrocardiogram. This scoring system correlates well with the size of anterior and inferior infarcts measured at autopsy when other factors such as previous infarcts, conduction disturbances, and ventricular hypertrophy are absent.[14,15]

In the present study, the QRS scoring system was used to analyze daily electrocardiograms of patients with acute inferior infarcts. The difference of at least 2 QRS points required for diagnosing a score change exceeds the observer variability previously documented in this laboratory.[13] Because all the observed changes during the first 3 days resulted in increased scores, and because the QRS score has been correlated with anatomic infarct size, it is likely that the observed increases indicate increasing necrosis.

Other explanations for QRS score changes cannot be excluded. One mechanism might be "infarct expansion," a process described by Hutchins and Bulkley,[20] in which the infarcted myocardial wall stretches and thins. This process potentially increases the proportion of infarcted myocardium exposed to surface electrodes, possibly altering the QRS complex. Such expansion, however, has been considered to become significant only by the fourth to fifth day after the onset of infarction. Almost all of the QRS changes observed in this study were noted during the second or third days. Moreover, infarct expansion has been observed much more frequently in patients with anterior infarcts; only 19% of the patients in the series of Hutchins and Bulkley[20] had inferior infarcts. On the basis of timing and location, therefore, it seems unlikely that many of the QRS changes observed in the present study resulted from infarct expansion.

Another possible cause of QRS change may be found in experimental studies which have identified increased extravascular fluid in infarcted myocardium.[21–23] Reimer and Jennings[21] have demonstrated in the canine model that this fluid can cause a 25% increase in infarct weight after 4 days. The fluid disappears after 28 days. Extravascular hemorrhage and edema might therefore have caused temporary QRS score increases during Days 5 to 7 of the present study, but very few changes were observed after Day 3. Extravascular fluid, like infarct expansion, occurs too late to correspond to the major period of QRS score change observed in the present study. Late electrocardiograms were unavailable, so resolution of QRS changes after 28 days could not be determined. A concurrent study in our laboratory, however, has documented minimal regression in QRS score during the initial 2 months after acute nonoperative infarcts.[24]

Ganz et al,[25] Beller et al,[26] and others[27,28] have performed experimental and clinical studies describing the sudden development of Q waves after myocardial reperfusion. These studies have shown that S-T segments diminish rapidly upon reperfusion, and Q waves concurrently increase. The investigators describing these events have suggested that Q waves may be "masked" by an injury current and "unmasked" by its resolution. In the present retrospective study, the relative timing of QRS change and S-T segment resolution could not be determined because of infrequent sampling. In experimental studies, however, Q waves have been shown to develop before injury currents resolve.[29] In addition, Q waves produced by coronary arterial occlusion were not diminished when reocclusion produced recurrent S-T segment elevation.[30] On the basis of these findings, it seems unlikely that QRS score changes result from injury current resolution.

The significance of QRS changes during the days after the onset of infarction remains uncertain. The changes probably reflect ongoing necrosis. Experimental studies in the canine model have yielded results which substantiate this possibility. A border zone of viable but ischemic tissue has been shown to exist within the perfusion field of an occluded vessel.[31–34] Lee et al[35] reported that this border zone may be of substantial size in man. Its source of perfusion is probably quite tenuous, being either collateral blood flow or flow through a highly stenosed epicardial vessel. In either circumstance, small disturbances in hemodynamic parameters may result in progressive myocardial necrosis during the early days after the onset of infarction. Unfavorable alterations in hemodynamic parameters may result in necrosis several days after the onset of infarction.

If ongoing necrosis is the determining factor in QRS score changes, such as those described in the present study, the infarction process may not be limited to a 24-hour period but may continue for 2 to 3 days in a significant proportion of patients. Moreover, among patients who are admitted with QRS scores of 0, the myocardium may not have undergone any necrosis before admission. Interventions initiated later than the first few hours after the onset of symptoms may have a greater potential for limiting infarct size than previously considered. Further investigation is required to determine the period in which such interventions can be effective. The standard 12-lead electrocardiogram may provide an important tool for evaluating interventions intended to limit infarct size, possibly with the goal of maintaining the minimal QRS score observed at the time of hospital admission.

Coronary and Left Ventricular Angiographic Anatomy and Prognosis of Survivors of First Acute Myocardial Infarction

ROBERT D. ABRAHAM, MB, GARETH S. ROUBIN, MB, PHILLIP J. HARRIS, MB, LOUIS BERNSTEIN, MB, and DAVID T. KELLY, MB

To relate coronary anatomy and left ventricular function to prognosis, 197 of 269 consecutive survivors of a first myocardial infarction (MI) ≤60 years old underwent prospective cardiac catheterization a median of 2 weeks after admission and were followed up for a median of 24 months (range 12 to 61). Seventy-two patients were excluded from angiography because of early death (9), severe noncoronary disease (44), MI complications (6), or patient refusal (13). The prevalence of multivessel disease was low (30%) and unrelated to the site of MI or presence of Q waves but was increased in patients with previous angina pectoris ($p = 0.05$) or those in Killip class II or III ($p = 0.02$). There were only 8 deaths from heart disease. The survival rate at 12 months was 97 ± 1% and at 24 and 36 months, 95 ± 2%. Nineteen patients underwent coronary revascularization surgery. As the number of deaths was small, the differences in survival between patients with single or multivessel disease and normal or depressed ejection fractions failed to reach significance. Survivors of a first MI ≤60 years old have a low prevalence of multivessel disease and a good prognosis.

Beta-blockade therapy has been shown to reduce mortality in survivors of myocardial infarction (MI) and is accepted practice. MI is not, however, a homogeneous entity, and subsets of patients with varying prognoses can be identified, determined by age, number of MIs, degree of left ventricular (LV) dysfunction, and extent of coronary artery disease (CAD).[1–6] This study was designed to assess outcome in a common and sociologically important subset of patients: those ≤60 years old who have had their first MI.

Methods

Patient group: From October 1976 to June 1981, 269 consecutive patients ≤60 years old were admitted with their first MI: 197 underwent coronary arteriography at a median time of 2 weeks (range 10 days to 16 weeks) and form the study cohort (Table I). MI was defined from 2 of 3 criteria: (1) prolonged chest pain typical of myocardial ischemia; (2) development of pathologic Q waves on the electrocardiogram; and (3) an increase in serum creatine kinase activity to at least twice the upper limit of normal with an increase in creatine kinase-MB isoenzyme activity. Patients were not considered for study if they had had a previous documented MI, had Q waves diagnostic of a previous MI on the electrocardiogram, were transferred from another hospital because of complications of MI, or had undergone previous coronary artery surgery. Forty-four were excluded because of severe noncoronary disease: neurologic disease (5), severe systemic hypertension or renal disease, or both (7), severe peripheral vascular disease (6), respiratory disease (5), psychiatric disorder (4), severe diabetes mellitus (4), valvular heart disease (6), cardiomyopathy (2), malignancy (2), severe rheumatoid arthritis (1), blood dyscrasia (1), and recent motor vehicle accident (1). Five patients were excluded because of acute complications. Thirteen patients refused to participate in the study. Three of the patients who had been excluded from angiography and 9 of the eligible patients died in the hospital.

Clinical parameters: Clinical data were collected prospectively on each patient and entered into a computerized information system. This consisted of a detailed history, daily physical examination throughout the hospital stay, chest radiography, and electrocardiogram.

Clinical characteristics: The median age of the 197 patients was 51 years (range 27 to 60). One hundred sixty-five (84%) were men and 32 (16%) were women. Sixty-four patients (32%) had a history of angina pectoris for at least 10 days before admission. Electrocardiograms showed anterior MI in 96 patients (49%) and inferior MI in 99 (50%). Two patients had left bundle branch block at admission. Q waves developed in

TABLE I Study Cohort

	Number
Patients admitted with first infarction	269
exclusions	
In-hospital deaths	9
Severe noncoronary disease	44
Complications precluding angiography	6
Patient refusal	13
Study patients	197

130 patients (66%). One hundred forty-nine patients were assessed as Killip class I (76%), 34 (17%) as class II and 14 (7%) as class III.

Catheterization and angiographic procedures: Coronary arteriography and left ventriculography were performed by the Sones and Judkins techniques. Cineangiograms were recorded in the right and left anterior oblique projections using axial views and read by 2 independent observers. LV ejection fraction (EF) was calculated for each patient using the area-length method.[7] In the right, left anterior descending and circumflex arteries, narrowing of >70% of the luminal diameter in any projection agreed by 2 observers was considered significant. Narrowing in large diagonal or obtuse marginal branches was classified as left anterior descending or circumflex disease, respectively. Left main coronary artery narrowing of >50% was regarded as significant. Only the most severe narrowing of each coronary artery was recorded and the patient classified as single-, 2-, or 3-vessel CAD.

Follow-up: After discharge, patients were followed up at 3, 6, and 12 months, and then annually to a median time of 24 months. The minimum follow-up time was 12 months. No attempt was made to influence management or drug therapy in this study. Patients were referred back to their own physician who supervised their medical care. The outcome was displayed on life tables with mean ± 1 standard error. Kaplan-Meier life table analysis[8] and log-rank testing[9] were used to compare outcome between groups. Patients who underwent surgery remained in the analysis up to that time and were then withdrawn from analysis alive.

Statistical analysis: Continuous data are expressed as mean ± 1 standard deviation and intergroup differences compared using the unpaired *t* test or 1-way analysis of variance when appropriate. Proportions are compared by the chi-square test with Yates' correction. A p value <0.05 was considered significant.

Results

Outcome: There were 10 deaths, of which 8 were due to heart disease. One death was due to ventricular fibrillation before discharge. Two deaths followed readmission with recurrent MI, 4 occurred suddenly out of the hospital and 1 was unwitnessed. The cumulative life-table survival for 197 patients (Fig. 1) was 97 ± 1% at 1 year, 95 ± 2% at 2 years, and 95 ± 2% at 3 years.

Relation of clinical findings to outcome: The mean age of the patients who died was 53 years. The following clinical variables were tested for their relationship to subsequent mortality: previous angina, infarct site, presence of Q waves, Killip class and development of ventricular tachycardia or fibrillation in the coronary care unit. None of these factors were significantly related to mortality.

Angiographic data: Single-vessel CAD was present in 123 patients (62%), 2-vessel CAD in 45 (23%), and 3-vessel CAD in 13 (7%). Sixteen (8%) had no vessel with >70% luminal diameter stenosis. Two patients had >50% stenosis of the left main coronary artery.

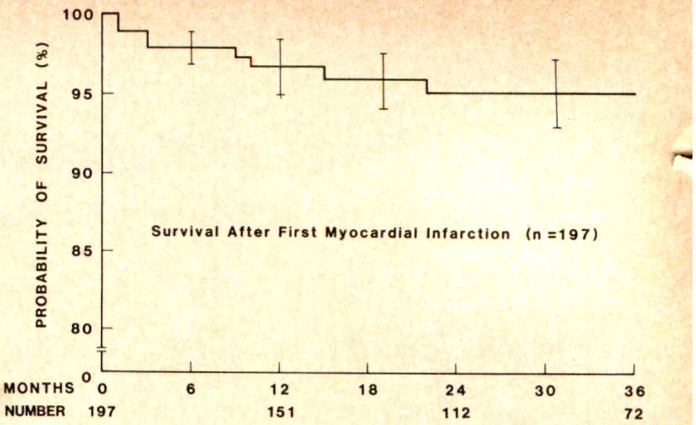

FIGURE 1. Cumulative life-table survival (± 1 standard error of the mean) for the total study group of 197 survivors of a first myocardial infarction aged ≤60 years.

The mean LVEF was 52 ± 13%. An EF ≥50% was found in 121 patients (61%), an EF of 40 to 49% in 45 patients (23%), an EF of 30 to 39% in 22 patients (11%), and an EF <30% in 9 patients (5%).

Relation of angiographic findings to outcome: The life-table survival of patients with single-vessel disease was 99 ± 1% at 1 year, 97 ± 2% at 2 and 3 years, and 97 ± 17% overall. There was no significant difference between the life-table survivals of patients with 2- and 3-vessel disease (chi-square = 0.003, difference not significant) and these were pooled as "multivessel disease." The life-table survival of patients with multivessel disease was 90 ± 5% at 1 year, 90 ± 6% at 2 years, 90 ± 7% at 3 years and 90 ± 28% overall (Fig. 2). The difference in life-table survival between patients with single and multivessel disease was not statistically significant ($0.14 > p > 0.025$).

The life-table survival of patients with LVEF ≥50% was 98 ± 14% and survival of those with EF <50% was 91 ± 28% ($0.1 > p > 0.05$) (Fig. 3).

Nineteen patients underwent coronary bypass surgery. Their mean age was 51 years. Eleven were in Killip class I, 6 in class II, and 2 in class III. Two had left main CAD, 5 had triple-vessel disease, 9 had double-, and 3 had single-vessel disease. The mean LVEF was 49 ± 14%. Both the patients with left main CAD and 2 with multivessel disease underwent surgery because of severe coronary disease despite only mild angina. Surgery was performed in 13 patients because of severe angina and 6 of these were operated on within 3 months of infarction. Two patients who had had cardiac failure associated with LV aneurysm underwent combined LV aneurysmectomy and coronary artery grafting.

Clinical findings and the prevalence of multivessel disease: The prevalence of multivessel CAD was significantly related to the presence of angina pectoris before infarction (Table II). Patients in Killip classes II and III had a higher incidence of multivessel disease than those in Killip class I (Table II). Although no patient <40 years old had 3-vessel CAD, the prevalence

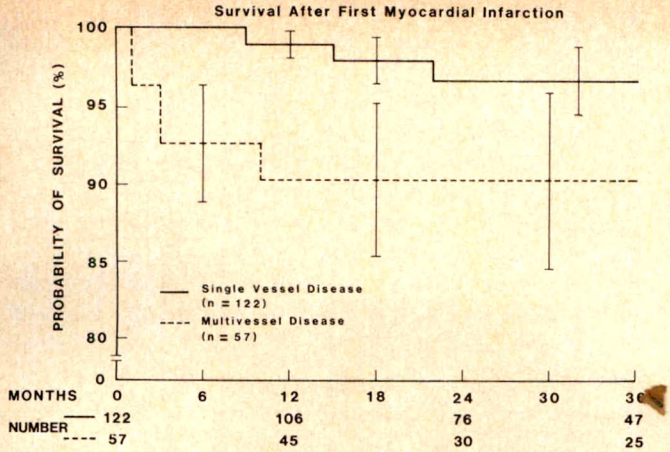

FIGURE 2. Life-table survival (±1 standard error of the mean) of patients with single- and multivessel disease.

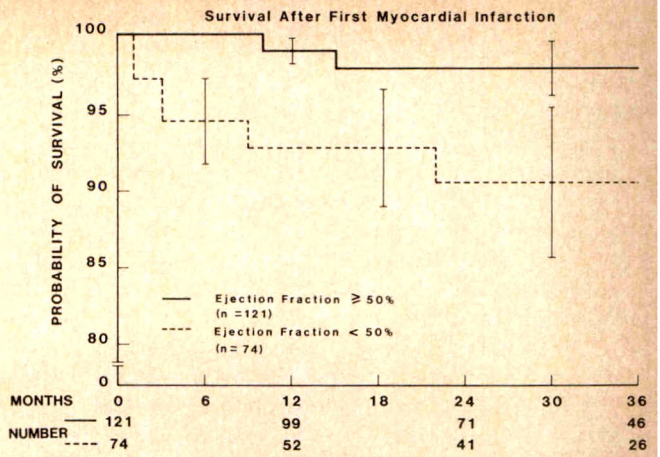

FIGURE 3. Life-table survival (±1 standard error of the mean) for patients with ejection fractions ≥50% and <50%.

of multivessel CAD was not significantly higher in patients >50 compared with those <50 years old. Neither the MI site nor the presence of Q waves altered the prevalence of multivessel disease.

Clinical findings and left ventricular ejection fraction: The mean LVEF decreased with increasing Killip class (Killip I, 55 ± 12%; Killip II, 47 ± 14%; and Killip III, 38 ± 14%) ($p < 0.01$) (Table III). Patients with Q-wave MI had a mean EF of 49 ± 13%, which was significantly lower than the 59 ± 11% mean EF of those with non–Q-wave MI ($p < 0.001$). LVEF was not related to the presence of angina before admission, age ≥50 years or <50 years, MI site or the occurrence of ventricular tachycardia, or ventricular fibrillation in the coronary care unit.

Discussion

This study describes the coronary anatomy and LV function and prognosis in 197 patients ≤60 years old who survived a first MI and underwent early, prospective cardiac catheterization.

There are 2 major findings in this study. First, there was a high (70%) prevalence of insignificant and single-vessel CAD. Second, the overall prognosis was good as only 8 patients died from heart disease during the follow-up period to a median time of 24 months.

The high prevalence of single-vessel or insignificant CAD results in part from the selection criteria for the study. Patients with previous MI and those >60 years old were excluded. Previous MI and advancing age have been shown to predict more severe CAD after MI.[10,11,13] Patients who were transferred from other hospitals because of complications were excluded. Patients with congestive heart failure, recurrent angina, and complex late arrhythmias have a high prevalence of multivessel CAD after MI.[10,11] If transferred patients are excluded, the patient population with acute MI tends to be from the surrounding geographic area. Because most hospitals that see and treat patients with MI receive patients from only the surrounding community, predictions of outcome should be made from this population rather than from the population referred and admitted to tertiary institutions.

A 5% annual mortality rate in males and a 7% rate in females <66 years old who had survived 30 days after an initial MI was reported from the community-based Framingham Study.[18] Recent studies report a better prognosis. Davis et al[2] found a 90 to 94% 3-year survival of patients <66 years old admitted to 2 community

TABLE II Clinical Findings and Prevalence of Multivessel Disease

Clinical Findings	n	Percent With MVD	p
Age ≤50 years	94	23	NS
Age >50 years	103	35	
Previous angina	133	39	0.05
No previous angina	64	25	
Killip II and III	48	44	0.02
Killip I	149	25	
Anterior MI	96	26	NS
Inferior MI	99	33	
Q-wave MI	129	31	NS
Non–Q-wave MI	66	24	

MI = myocardial infarction; MVD = multivessel disease; NS = not significant.

TABLE III Clinical Findings and Left Ventricular Ejection Fraction

Clinical Findings	LVEF (Mean ± SD)	p
Age ≤50 years	53 ± 14	NS
Age >50 years	52 ± 14	
Previous angina	53 ± 15	NS
No previous angina	52 ± 12	
Killip I	55 ± 12	
Killip II	47 ± 14	<0.01
Killip III	38 ± 14	
VT or VF in CCU	50 ± 17	NS
No VT or VF in CCU	53 ± 13	
Anterior MI	51 ± 14	NS
Inferior MI	54 ± 12	
Q-wave MI	49 ± 13	<0.001
Non–Q-wave MI	59 ± 11	

CCU = coronary care unit; LVEF = left ventricular ejection fraction; MI = myocardial infarction; NS = not significant; SD = standard deviation; VF = ventricular fibrillation; VT = ventricular tachycardia.

hospitals with a first MI after high-risk patients had been excluded. Barnaby and Norris[19] reported a 4.5% death rate in the first year after first MI in men <60 years old, with a 3% annual mortality in years 2 to 4.

Because the death rate in our study is so low we have not been able to draw statistically significant conclusions about either clinical or angiographic predictors of mortality. The good prognosis reflects in part the low prevalence of multivessel CAD, which is a major determinant of death, both in patients with chronic CAD[4–6] and in survivors of MI.[12,13]

Other prospective studies of coronary anatomy after MI[10–13] have reported a higher prevalence of multivessel CAD. This ranged from 59% after first or subsequent MI[12] to 68% after first MI.[11] Most of these studies did not specify the proportion of referred, complicated patients, although De Feyter et al[13] excluded referred patients and found a 53% prevalence of multivessel CAD in a population of first MI survivors up to 65 years old.

Some investigators define 50% diameter stenosis as the lower limit for "significant" CAD,[10,12,13] whereas we and other investigators[11,14] accept >70% diameter stenosis. Analysis or our angiograms in terms of 50% diameter stenosis yields 3% insignificant disease, 52% single-vessel CAD, 30% double-vessel, and 16% triple-vessel disease.

The presence of multivessel CAD was poorly predicted by the infarct site, as reported by other prospective studies of coronary anatomy after infarction.[10,11] Several nonprospective series[14–16] have reported a higher prevalence of multivessel disease after inferior MI, but included patients referred for angiography because of post-MI angina. However, De Feyter et al,[13] in their prospective study, reported a significantly higher prevalence of multivessel disease after first inferior MI than after anterior MI.

A history of angina before or cardiac failure after MI increased the probability of multivessel disease, as has previously been reported,[10,11,15] but neither was a sensitive predictor of anatomy.

The exclusion of 44 patients with serious noncoronary conditions, especially hypertension, renal failure, or diabetes, may have reduced the prevalence of multivessel disease and, consequently, reduced the cardiac mortality in the study population.

The outcome of our patients may have been influenced by the current attitudes to management of CAD, whereas no attempt was made to influence the physicians who cared for the patients in this study. Nineteen patients underwent coronary surgery, 2 with left main CAD and 2 others because of severe coronary lesions but few symptoms. Thirteen underwent surgery because of severe angina pectoris and 2 because of LV aneurysms with associated heart failure. Forty-five percent received beta-blocking drugs after discharge. Beta-blocking drugs may have influenced the outcome[17,20,21] but, in the timolol trial[21] there was no reduction in mortality in uncomplicated survivors of first MI who received drug treatment. Although both the surgical and medical therapy may have altered the outcome in these patients, their contribution cannot be determined; nevertheless they reflect the usual management of patients after MI today.

The present study suggests that patients ≤60 years who survive their first MI have a low prevalence of multivessel CAD and a good prognosis.

Coronary Arterial Aneurysm Formation After Balloon Angioplasty

JAMES A. HILL, MD, JAMES R. MARGOLIS, MD, ROBERT L. FELDMAN, MD, C. RICHARD CONTI, MD, and CARL J. PEPINE, MD

The mechanism of coronary stenosis dilatation by percutaneous transluminal coronary angioplasty (PTCA) is incompletely understood. Five men who developed coronary arterial aneurysms at the site of PTCA are described. All patients were in New York Heart Association functional class III or IV at the time of PTCA. In 2 patients acute myocardial infarction was evolving and both had acute coronary occlusion. The other 3 patients had angiographic evidence of intimal disruption or acute coronary reocclusion as a result of PTCA, one of whom had undergone emergency coronary artery bypass grafting. Three patients received intracoronary streptokinase during PTCA. One patient was asymptomatic and 4 were symptomatic when the aneurysms were identified between 11 days and 4 months after PTCA. Other than the complex course and anatomy of these patients before and immediately after PTCA, no other features distinguished them from others undergoing this procedure.

The improvement in coronary artery size after percutaneous transluminal coronary angioplasty (PTCA) is presumably due to some degree of plaque compression-disruption and injury to various layers of the vessel wall.[1] Cadaver and animal studies suggest that acute effects of dilatation involve intimal and medial layers.[1–6] Limited information is available, however, regarding coronary artery remodeling over time as a result of this "controlled" injury. Coronary artery occlusion and dissection-disruption immediately after PTCA have been reported, but to our knowledge, aneurysms at the site have not been described.[7] This study describes formation of coronary arterial aneurysm after PTCA in 5 patients.

Methods

Patients: Five men who underwent PTCA for angina were studied. All had important stenoses at angiography that persisted after administration of nitroglycerin. Coronary stenosis was quantified and PTCA was done as described by Grüntzig et al,[8] with modifications as noted. Appropriately sized guiding and dilatation catheters were chosen based on vessel size and location of stenosis. Heparin, nitroglycerin, low-molecular-weight dextran and nifedipine (except in Patient 1) were administered during PTCA; aspirin, dipyridamole, and long-acting nitrates were given after the procedure. During the 3-year period when these patients were seen, more than 450 PTCA procedures were done at our institution and more than 200 were followed up with repeat angiography. All patients gave informed consent and investigational aspects of PTCA were approved by appropriate institutional review committees. Pertinent features of these cases are summarized in Table I.

Patient 1 had angina for 4 years. After undergoing left anterior descending artery (LAD) bypass surgery, he did well for >4 years and then developed unstable angina. Four hours after he had an acute inferior myocardial infarction, the right coronary artery was found totally obstructed after intracoronary nitroglycerin (Fig. 1). After guide wire recanalization without difficulty, subtotal (99%) occlusion persisted. Streptokinase (122,000 U) was administered over 56 minutes into the right coronary artery but 95% occlusion persisted. PTCA was done without difficulty (Table I), but 50% stenosis remained without angiographic evidence for coronary dissection or aneurysm (Fig. 1). At elective follow-up study performed 2 months later, the patient was asymptomatic, with normal left ventricular hemodynamic function, minimal inferior hypokinesia greatly improved, and an aneurysm localized to the dilatation site (Fig. 1).

Patient 2 had exertional angina for 9 months which increased in frequency and severity over several weeks. He had obstruction only in the mid-LAD (Fig. 2). After PTCA, performed without difficulty, minimal residual stenosis persisted (Table I) with a short linear luminal defect at the dilatation

* All patients received heparin, nitroglycerin, and low-molecular-weight dextran.
AMI = acute myocardial infarction; atm = atmospheres; CABG = coronary artery bypass grafting; LAD = left anterior descending artery; MISC = miscellaneous; PTCA = percutaneous transluminal coronary angioplasty; RCA = right coronary artery.

site. Within 4 months, angina developed and increased in severity. The LAD now had sequential stenoses with an aneurysm at the dilatation site (Fig. 2). Bypass surgery was performed but the patient required continued antianginal medication.

Patient 3 had an anterior myocardial infarction and developed progressive angina over the next year. He had proximal LAD stenosis involving a large diagonal branch (Fig. 3). After PTCA, performed without difficulty, minor irregularities were seen at the area of previous stenosis with slow contrast filling of the diagonal branch. Because these irregularities suggested thrombus, streptokinase (15,000 U) was injected into the LAD. He did well, but after 4 months exertional angina recurred. The LAD had irregularity at the dilatation site and an aneurysm proximal to the origin of the previously involved diagonal branch. Slow contrast filling of the diagonal branch with narrowing proximally persisted (Fig. 3).

Patient 4 had recent onset angina, S-T segment depression at low-level exercise, and 90% proximal LAD stenosis (Table I). At PTCA, difficulty advancing the balloon across the stenosis occurred, so the catheter was withdrawn. Angina developed and decreased contrast flow in the LAD appeared and persisted after intracoronary nitroglycerin was given. A smaller balloon catheter (DG20-20) was advanced across the stenosis without difficulty. After 4 inflations it was replaced with a larger (DG20-30) catheter. Multiple inflations decreased the pressure gradient and severity of stenosis but a double lumen and poor distal contrast flow resulted. Because of persisting angina with S-T and T-wave changes, an intraaortic balloon pump was inserted and bypass surgery performed using the internal mammary artery. No evidence for perioperative myocardial infarction evolved. On the third postoperative day, 2 episodes of angina occurred. Eleven days postoperatively the mammary graft to the mid-LAD was patent, but proximally an aneurysm was localized to the site of the LAD angioplasty and total occlusion had developed just distal to the aneurysm.

Patient 5, with angina rapidly accelerating in frequency and severity over 2 weeks, had long 95% proximal and 50% mid-LAD obstructions. The next day, 5 hours after the onset of an acute anterior myocardial infarction, total LAD occlusion was found at the site of previously demonstrated proximal stenosis. After intracoronary administration of streptokinase (60,000 U), the LAD reopened with 75% residual stenosis. After PTCA, the LAD was widely patent with a linear luminal defect localized to the dilatation site, and a routine electrocardiogram taken in the coronary care unit showed anterior-lead S-T-segment elevation. Repeat angiography now revealed total LAD occlusion and a 3F Teflon® catheter was advanced across the occlusion without difficulty. Intracoronary nitroglycerin and streptokinase reopened the LAD artery, but enzyme and electrocardiographic changes of anterior myocardial infarction evolved. Two weeks later 30% proximal LAD occlusion at the dilatation site and 2 other areas of approximately 40% occlusion were present. At the dilatation site there was evidence for dissection but not aneurysm. Angina recurred after discharge and 3 months later angiography revealed that the 30% proximal LAD occlusion was unchanged. Distal to this stenosis, at the previous dilatation site, there was a long (approximately 2 cm by 5 mm) aneurysm followed by 50% stenosis (Table I).

Clinical and angiographic characteristics: Other than severe symptoms related to coronary artery disease, there were no clinical factors such as hypertension, diabetes, and other conditions that made this particular group different from other patients who had undergone PTCA as represented by the Registry of the National Heart, Lung, and Blood Institute.[9] None of these patients had distal stenosis, so the dilating

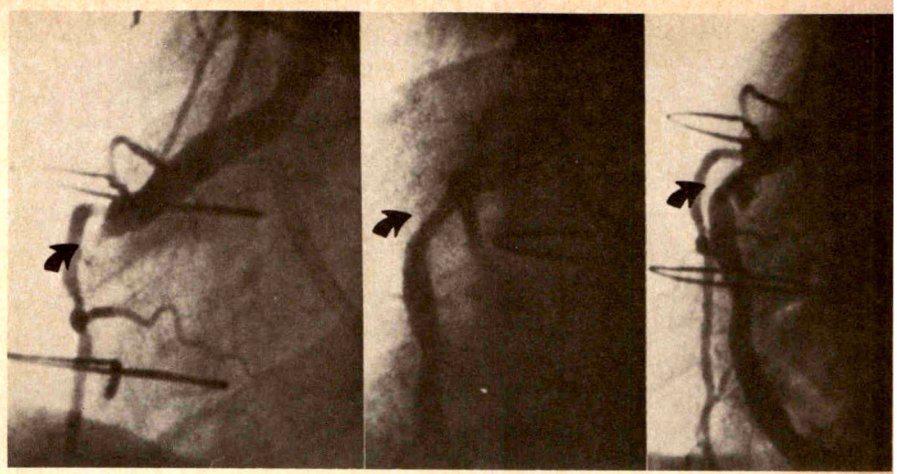

FIGURE 1. Case 1. Right coronary angiogram in left anterior oblique projection. **Left,** after intracoronary nitroglycerin but before streptokinase infusion and percutaneous transluminal coronary angioplasty (PTCA); **middle,** immediately after PTCA; **right,** 2 months after PTCA. **Arrows** indicate site of dilatation.

catheter was not advanced over a long distance within the coronary artery. In no patient did the balloon diameter appear to exceed the diameter of the native vessel viewed just proximal to the stenosis.

All patients received heparin, continuous infusions of nitroglycerin and low-molecular-weight dextran; 4 patients (Cases 2 to 5) received buccal nifedipine. However, 3 patients (Cases 1, 3, and 5) received intracoronary streptokinase during PTCA, with total doses of 15,000 to 122,000 IU. Administration of aspirin, dipyridamole, and nitrates was continued after PTCA.

Within hours of the dilatation procedure, 2 patients (Cases 1 and 5) had occlusion of the vessel undergoing PTCA. The other 3 had evidence of intimal disruption or abrupt reocclusion. There was no evidence at follow-up to suggest rupture of these aneurysms.

Results

Technical considerations: All patients had single-vessel PTCA performed by way of the femoral approach. In 2 patients (Cases 4 and 5) the guide catheter

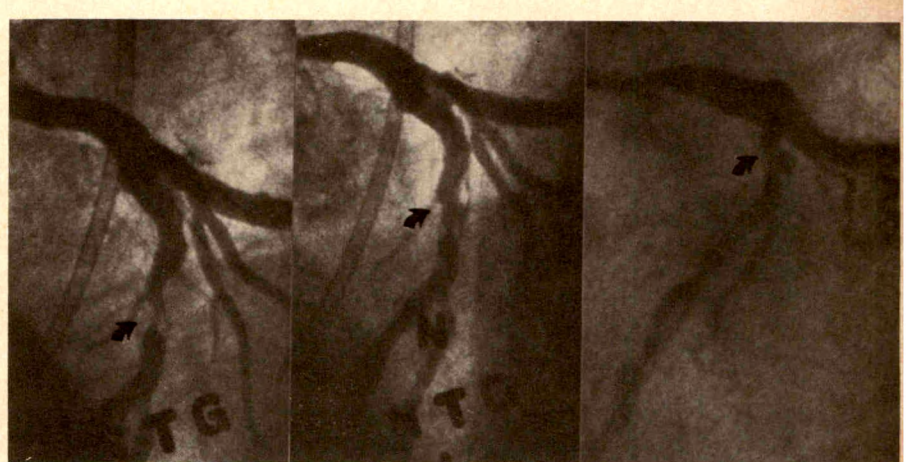

FIGURE 2. Case 2. Left coronary angiogram in left anterior oblique projection. **Left,** before percutaneous transluminal coronary angioplasty (PTCA); **middle,** immediately after PTCA; **right,** 4 months after PTCA. **Arrows** indicate site of dilatation.

as advanced deep into the left main coronary artery LAD to control the dilating catheter, but aneurysms veloped several centimeters beyond the guide cath-er. Commercially available dilating catheters, without novable guide wire, were used. Difficulty passing the lloon catheter across the stenosis occurred in only 1 tient (Case 4). All patients had multiple inflations (5 7 atmospheres) at the site of subsequent aneurysm rmation. There were no coronary artery perforations, ptured balloons, or emboli. Evidence of coronary asm was absent. In no patient was the dilatation a peat procedure.

Clinical course: At follow-up examination, 4 pa-nts had angina, prompting bypass surgery and drug erapy in 1 (Case 3). The other patient (Case 1) was ymptomatic at follow-up. The time to follow-up theterization, which first detected aneurysm forma-n, was 11 days to 4 months after PTCA. One patient ase 5) underwent cardiac catheterization 2 weeks ter PTCA and again at 3 months, but the aneurysm as present only at 3 months.

Discussion

These patients represent a very select group under-ing PTCA. These patients had complex clinical and atomic conditions and a high rate of complications. hether other clinical or technical differences were esent among these and other patients undergoing TCA without aneurysm formation is difficult to as-rtain. All these patients had an acute change related the coronary artery selected for PTCA, which is not aracteristic of most patients selected for this proce-re. Before PTCA, 2 patients had complete thrombotic clusions and another had a suspected nonocclusive rombotic defect, and intracoronary streptokinase was ven. Whether these circumstances contributed to neurysm formation is not known.

The complication rate with PTCA is 18.5%,[9] but to r knowledge formation of coronary arterial aneurysm the site of PTCA has not been reported. Follow-up theterizations are not done routinely in many centers, hich could account for lack of detection in some cases. he aneurysm would not have been detected in Patient if he had not undergone a second catheterization as art of follow-up, because he was asymptomatic.

The mechanism of improvement in coronary luminal ameter from PTCA is complex and includes plaque sruption, rupture of fissures, endothelial desquama-on and compression. Animal models show loss of en-othelium, plaque fracture with and without dissec-on-disruption of the internal elastic membrane, and atelet deposition.[3,4,5,10] In these animal studies there ere no acute occlusions but aneurysm formation oc-rred in 1 animal.[3] Human cadaver coronary arteries ith postmortem balloon angioplasty show medial and timal disruption.[2] Smooth muscle and medial con-ective tissue disruption occurs.[6] There are limitations trapolating these observations to live subjects. The ntributions of smooth muscle tone, motion, blood ow, and the healing process are unclear. The time urse of anatomic changes induced by PTCA is also known. Immediately after PTCA, a "hazy" con-ast-lumen interface often is seen at the site of angio-plasty.[1] This clears by the time of follow-up studies and perhaps represents intimal injury (edema, hemorrhage, and other factors) that heal over time. Small areas of linear radiolucency are also often seen immediately after dilatation. Whether this represents intimal disruption caused by separation of plaque fissures or intimal and medial dissection (that is, hematoma) remains unknown. Precisely what happens, over the long term, in areas where more extensive injury (such as dissection and occlusion) occurs is also unknown. The latter has particular relevance to our cases, because no evidence for aneurysm formation was present immediately after dilatation.

Whether initial local damage occurred coincident with exacerbation in symptoms that preceded or was secondary to PTCA cannot be determined. One could speculate, however, that PTCA-related damage caused medial weakening or disruption and the persistent hemodynamic stress dilated the weakened arterial wall. The fate of these PTCA-related aneurysms is unknown. Some have speculated that coronary aneurysms lead to embolization or thrombosis.[11–13] Rupture of a coronary aneurysm occurring in the natural course of coronary atherosclerosis is rare, if it occurs at all. PTCA-related aneurysms could have a different fate, however, if trauma or inflammation or both contributed to aneurysm development. Development of coronary aneurysm after PTCA emphasizes that our understanding of this new procedure is limited.

New and important evidence affirms the

Slow-K®

potassium chloride slow-release tablets 8 mEq

8-year U.S. record of clinical experience.

Please see last page for brief Prescribing Information.

New endoscopic studies show:

No significant difference in GI lesions between

Slow-K®
potassium chloride slow-release tablets 8 mEq

and Micro-K®
potassium chloride controlled-release Extencaps® 600 mg 8 mEq K

SLOW-K: UNSURPASSED FOR SAFETY AMONG SLOW-RELEASE KCl CAPSULES OR TABLETS

Maximum-dosage (96 mEq) multistudy data*

Results: No significant differences in endoscopic changes found between Slow-K and Micro-K at 96-mEq dosage.†

(Administered as four 8-mEq tablets or capsules, t.i.d.)

These data resulted from four different studies (involving 64 subjects) that used the maximum recommended daily dosage of 96 mEq before food ingestion and with concomitant administration of the maximum recommended dosage of the anticholinergic agent glycopyrrolate (6 mg).[1-4]

Maximum-dosage multistudy data

					Endoscopic findings‡			
N	Treatment	Daily dosage	Glycopyrrolate	Food	Ulcers	3	2	1
27	Slow-K	96 mEq	6 mg	No	1	1	6	12
37	Micro-K	96 mEq	6 mg	No	2	1	2	9

Results from similar studies supported by the A.H. Robins Company have shown a greater incidence of endoscopically observed GI irritation with Slow-K as compared to Micro-K when maximum doses of glycopyrrolate are administered.[5,6] These results, showing a significant difference between the products, are *inconsistent* with the data described herein, which do not show a significant difference.

High-dosage (48 mEq) multistudy data*

Results: No ulcers found with Slow-K or Micro-K. No significant differences in endoscopic changes found with Slow-K and Micro-K at 48-mEq dosage.

(Administered as two 8-mEq tablets or capsules, t.i.d.)

These data resulted from two different studies (involving 36 subjects) that used the high (48 mEq) dosage with food ingestion, and with and without the maximum recommended dosage of the anticholinergic agent glycopyrrolate. (Note: Glycopyrrolate was used in only one group of subjects on Slow-K.)[1,2] This 48-mEq dosage is higher than that normally used prophylactically.

High-dosage multistudy data

					Endoscopic findings‡			
N	Treatment	Daily dosage	Glycopyrrolate	Food	Ulcers	3	2	1
12	Slow-K	48 mEq	6 mg	Yes	0	0	2	6
12	Slow-K	48 mEq	None	Yes	0	0	0	4
12	Micro-K	48 mEq	None	Yes	0	0	1	5

*These studies were conducted by Drs. D. Patterson and G. Jeffries of the Hershey Medical Center, and by Dr. D. Earnest of the University of Arizona (Tucson).

†Also included in these multistudy data were an additional 70 subjects taking an 8-mEq sustained-release KCl capsule, a K^+ elixir, a sustained-release KCl tablet of higher mEq dosage than that currently available, or a placebo. The elixir and the placebo did not produce any endoscopic changes greater than two Grade 1 and five Grade 1 endoscopic findings, respectively. The higher dose sustained-release KCl tablets produced two ulcers, two Grade 2 and six Grade 1 endoscopic findings. The 8-mEq sustained-release capsule produced two Grade 2 and two Grade 1 findings. All Grade 1 endoscopic changes were considered clinically meaningless.

‡Grade 0 = no endoscopic findings
1 = hyperemia and/or edema (the medical consensus is that this category is clinically meaningless)
2 = few erosions
3 = numerous erosions (>3)
4 = ulceration
5 = multiple ulcerations

The anticholinergic agent glycopyrrolate was given to slow gastric emptying, thus ensuring maximum contact of the KCl supplements with the gastric mucosa. The impact, if any, of high-dose glycopyrrolate on the gastric mucosa is unknown.

Please see last page for brief Prescribing Information.

CIBA

New epidemiologic study shows:

No difference between

Slow-K®
potassium chloride slow-release tablets 8 mEq

use and no K^+ therapy in the incidence of upper GI bleeding in a hospital setting.

SLOW-K: UNSURPASSED FOR SAFETY AMONG SLOW-RELEASE KCl CAPSULES OR TABLETS

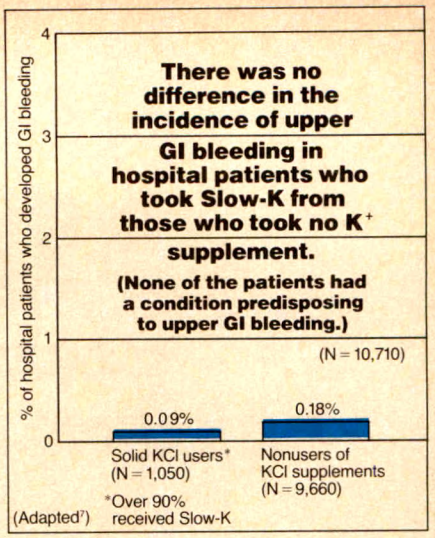
Experience of the Boston Collaborative Drug Surveillance Program[7]
As reported by Aselton and Jick in *Lancet*, January 22, 1983

Purpose of epidemiologic study:
To evaluate the relation between the use of wax-matrix KCl and the development of upper GI bleeding while in the hospital.

Patient population:
A total of 15,791 medical inpatients. Of those, 10,710 had no condition predisposing to upper GI bleeding. Of those, 1,050 received solid KCl* by mouth; 9,660 received no solid KCl.

Findings:
Of the 1,050 KCl users, 1 had GI bleeding (0.09%).
Of the 9,660 nonusers, 17 had GI bleeding (0.18%).

*Over 90% of this group received KCl in the form of Slow-K tablets.



Conclusion: "These findings argue against a positive association between wax matrix KCl use and upper gastrointestinal bleeding over a short period of time."[7]

These new data are consistent with the overwhelming evidence compiled in 8 years of use with Slow-K® potassium chloride slow-release tablets 8 mEq.

Analysis of 5.6 million U.S. patient-years' data: approximately one GI lesion per 100,000 patient-years—and this incidence rate has remained unchanged since Slow-K was introduced in 1975.[8]

*Method of determining incidence:
A: Includes all cases (most conservative method)
B: Excludes cases in which causality was unlikely and/or Slow-K was contraindicated
C: Excludes cases in which B was present *and* in which data were insufficient to assess causality (least conservative method)

Summary of lesion incidence rates per 100,000 patient-years

	Method* A	B	C
Esophagus	0.14	0.02	0.02
Stomach	0.27	0.14	0.11
Duodenum	0.12	0.05	0.05
Small bowel/large bowel; unknown location	0.82	0.43	0.27
Total	1.36	0.64	0.44

(Adapted[8])

Conclusion: Slow-K is a safe agent.

Capsule or tablet slow-release potassium chloride preparations should be reserved for patients who cannot tolerate, refuse to take or have compliance problems with liquid or effervescent potassium preparations, because of reports of intestinal and gastric ulceration and bleeding with slow-release KCl preparations.

Please see last page for brief Prescribing Information.

SLOW-K®
potassium chloride **slow-release tablets**

Brief Summary of Prescribing Information

DESCRIPTION
Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS
BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.
1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS
Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).
Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.
All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS
Hyperkalemia: In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.
The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.
Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.
Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains approximately one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.
Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS
The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

ADVERSE REACTIONS
The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.
One of the most severe adverse effects is hyperkalemia (see Contraindications, Warnings and Overdosage). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION
The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.
Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

How thorough and unbiased is your drug reference?

If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Gonzales, R.Ph., B.S. Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:
- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:
- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

The LifeSigns Monitoring System: An affordable investment in arrhythmia surveillance systems.

Transtelephonic arrhythmia monitoring and ECG transmission. Concepts pioneered by Instromedix can now be economically applied to documentation of transient arrhythmias, drug dosage titration and post-myocardial infarction surveillance through the LifeSigns Monitoring System.™

The System includes easy-to-use, diagnostic-accuracy transmitters like the CardioDiary® that records up to three separate 32-second ECG samples into solid state memory. The Cardiotel® II offers single-lead, real time ECG transmission at an attractive price. Cardiotel®III permits AHA diagnostic-quality documentation of Lead I, II, or III—at the push of a button.

The LifeSigns Receiving Center™ is the most advanced receiving station available for telephonic transmissions. Optional direct telephone line connection increases accuracy. Analysis, interpretation and storage of patient data are simplified by an RS-232 computer interface port and rhythm strip margin printing options.

The Tape-A-Trace® 2400 automatically receives, records and stores transtelephonic patient messages and ECGs, helping physicians keep in touch with patients, and freeing technicians and nurses for other tasks.

Standard ECG machines become a transtelephonic system for remote referral and follow-up with the 12 Lead Transmitter™ and 12 Lead Coupler.™

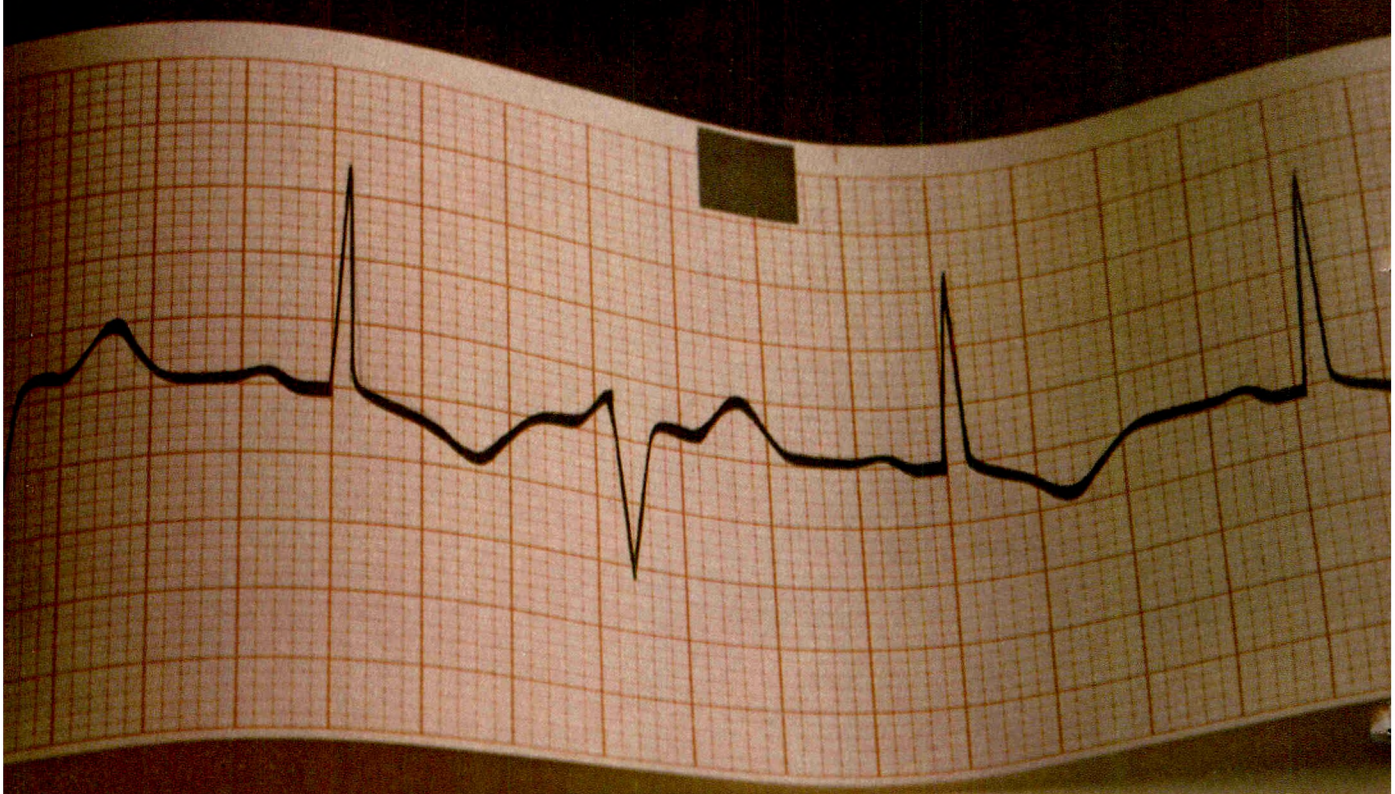
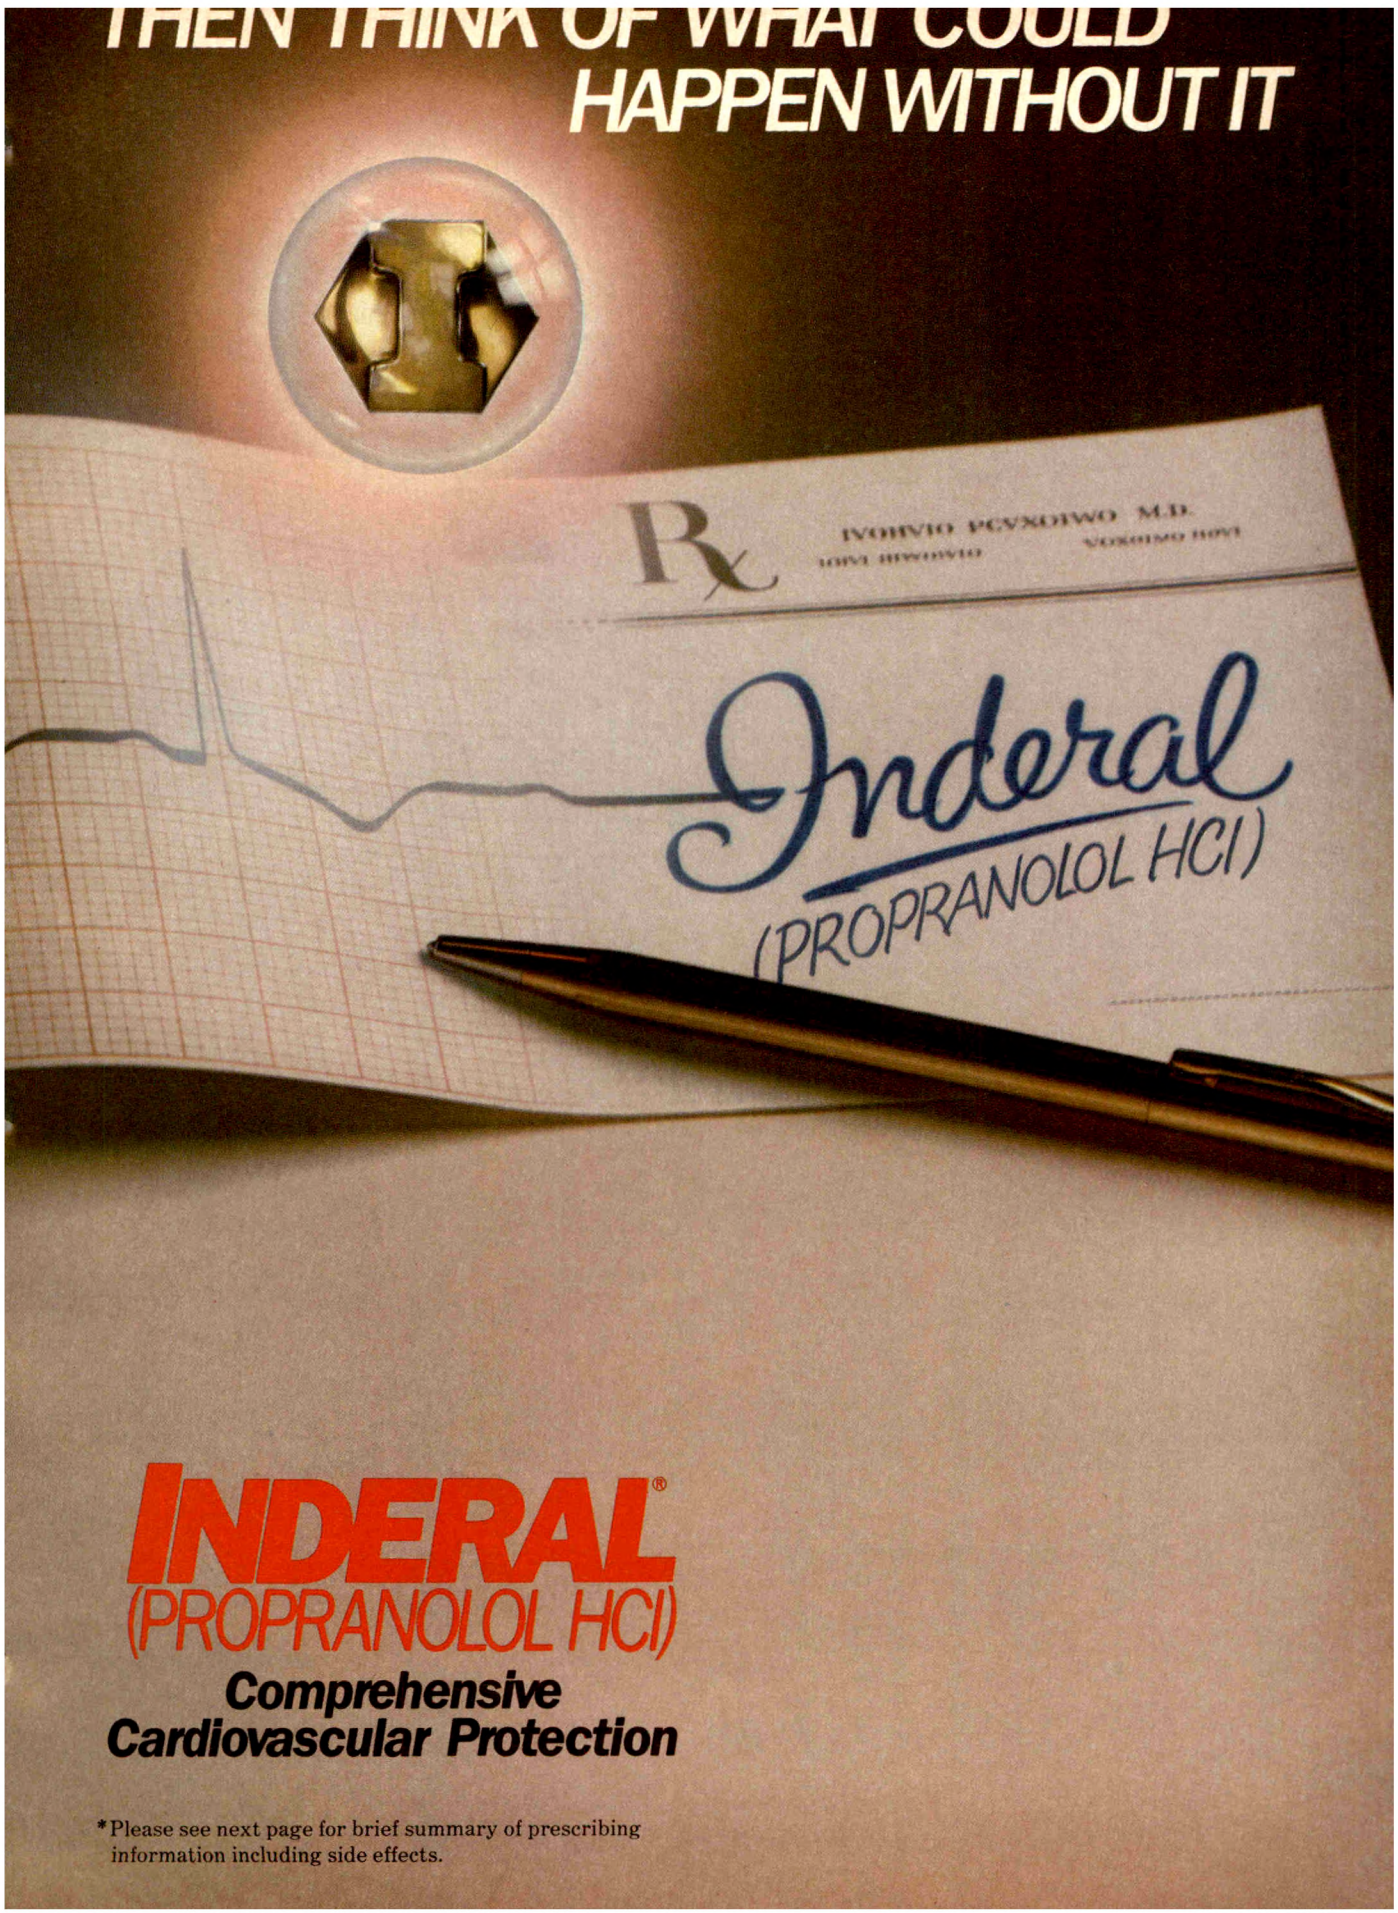
ARRHYTHMIAS
FIRST THINK OF INDERAL®
(PROPRANOLOL HCl)



Inderal—a primary agent for the control of many arrhythmias.

INDERAL is effective in a broad range of arrhythmias. Consider INDERAL first for a variety of supraventricular arrhythmias. While ventricular arrhythmias do not respond as predictably as supraventricular arrhythmias, INDERAL is often considered as drug of first choice for ventricular arrhythmias induced by catecholamines or digitalis.

INDERAL is uniquely suited for long-term prophylaxis...it is an antiarrhythmic agent that offers a particularly favorable side effects profile*...and INDERAL is the only beta blocker indicated for the treatment of arrhythmias *and* coexisting angina and hypertension.



INDERAL®
(PROPRANOLOL HCl)

Comprehensive Cardiovascular Protection

*Please see next page for brief summary of prescribing information including side effects.

INDERAL®
(PROPRANOLOL HCl)
FOR ARRHYTHMIAS
THINK OF IT FIRST.

The appearance of these tablets is a trademark of Ayerst Laboratories.

IEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
eral® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

pranolol hydrochloride is contraindicated in 1) bronchial asthma; 2) allergic rhinitis during pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic ock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart ure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with pranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO ibitors), and during the two week withdrawal period from such drugs.

WARNINGS

RDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory ction in congestive heart failure, and inhibition with beta blockade always carries the tential hazard of further depressing myocardial contractility and precipitating cardiac fail-. Propranolol acts selectively without abolishing the inotropic action of digitalis on the art muscle (i.e., that of supporting the strength of myocardial contractions). In patients eady receiving digitalis, the positive inotropic action of digitalis may be reduced by pro-anolol's negative inotropic effect. The effects of propranolol and digitalis are additive in pressing AV conduction.

N PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the ocardium over a period of time can, in some cases, lead to cardiac failure. In rare tances, this has been observed during propranolol therapy. Therefore, at the first sign or mptom of impending cardiac failure, patients should be fully digitalized and/or given a iuretic, and the response observed closely: a) if cardiac failure continues, despite adequate gitalization and diuretic therapy, propranolol therapy should be immediately withdrawn; b) if hyarrhythmia is being controlled, patients should be maintained on combined therapy and patient closely followed until threat of cardiac failure is over.

N PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of propranolol therapy. Therefore, when discontinuance of propranolol is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when propranolol is prescribed for angina pectoris, the patient should be cautioned against nterruption or cessation of therapy without the physician's advice. If propranolol therapy s interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute propranolol therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent o follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

N PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long-term use ve not been adequately appraised. Special consideration should be given to propranolol's tential for aggravating congestive heart failure. Propranolol may mask the clinical signs of veloping or continuing hyperthyroidism or complications and give a false impression of provement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbaon of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withawing propranolol slowly. Propranolol does not distort thyroid function tests.

N PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been orted in which, after propranolol, the tachycardia was replaced by a severe bradycardia quiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

N PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the art to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery at which time all chemical and ysiologic effects are gone according to available evidence. However, in case of emergency rgery, since propranolol is a competitive inhibitor of beta-receptor agonists, its effects can reversed by administration of such agents, e.g., isoproterenol or levarterenol. However, ch patients may be subject to protracted severe hypotension. Difficulty in restarting and intaining the heart beat has also been reported.

N PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), propranolol should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to keep in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of propranolol in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. Embryotoxic effects have been seen in animal studies at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if propranolol is administered. The added catecholamine-blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of propranolol may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

INDERAL (propranolol hydrochloride)

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains **10 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains **20 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains **40 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

—Each hexagonal-shaped, pink, scored tablet is embossed with an "I" and imprinted with "INDERAL 60," contains **60 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0426-81) and 1,000 (NDC 0046-0426-91). Also in unit dose package of 100 (NDC 0046-0426-99).

—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains **80 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

The Automatic Implantable Defibrillator: Local Ventricular Bipolar Sensing to Detect Ventricular Tachycardia and Fibrillation

ROGER A. WINKLE, MD, STANLEY M. BACH, Jr., MD, DEBRA S. ECHT, MD, CHARLES D. SWERDLOW, MD, MIR IMRAN, MSEE, JAY W. MASON, MD, PHILIP E. OYER, MD, PhD, and EDWARD B. STINSON, MD

The first-generation automatic implantable defibrillator implanted in man sensed arrhythmias by monitoring a transcardiac electrocardiographic signal. This sensing system reliably detected ventricular fibrillation and sinusoidal ventricular tachycardia but failed to sense all nonsinusoidal ventricular tachycardias. To solve this problem, a new ventricular tachycardia detection scheme was developed using a local ventricular bipolar electrogram and electronic circuits using rate averaging and automatic gain control to permit sensing of electrograms down to 0.1 mV. This detection scheme was tested during electrophysiologic studies in 11 patients with ventricular tachycardia and fibrillation. All 22 episodes of induced ventricular tachycardia with a rate above the selected cutoff were detected after an average of 5.1 ± 1.8 seconds. No episodes below the rate cutoff were detected. The bipolar circuits also reliably detected ventricular fibrillation. Arrhythmia detection and signal quality in 9 patients receiving automatic defibrillators using the new bipolar rate detection circuit were compared with the findings in 5 patients previously receiving units that sensed arrhythmias using the transcardiac electrocardiographic signal. Compared with the transcardiac monitoring units the newer bipolar units had shorter and more uniform sense times (5.5 ± 1.4 versus 12.2 ± 7.1 seconds). It is concluded that malignant ventricular tachyarrhythmias can be sensed accurately using bipolar rate detection and that this system has numerous advantages over the previously used transcardiac electrocardiographic signal.

Observations made in coronary care units in patients with acute myocardial infarction and the rhythms identified in out-of-hospital cardiac arrest victims at the time of arrival of paramedic units suggested that ventricular fibrillation (VF) was responsible for most of these deaths. These observations led Mirowski et al[1] to propose the concept of an automatic implantable defibrillator. This group demonstrated that defibrillation using catheters and other electrode configurations was possible in both animals[2] and man[3] using energy levels considerably below those required for transthoracic cardioversion. Early versions of the automatic defibrillator were designed to distinguish between VF or sinusoidal ventricular tachycardia (VT)[4] and supraventricular or nonsinusoidal VT. This was accomplished using an electrocardiographic signal derived from an extrapericardial patch sutured to the apex of the heart and a superior vena caval spring electrode (the same leads used for delivering the defibrillation shock). A probability-density function describing the relative durations of isoelectric and nonisoelectric activity of the signal was determined electronically to identify VF which produces a predominantly nonisoelectric signal. In the late 1970s, arrhythmia induction using programmed electrical stimulation in survivors of out-of-hospital cardiac arrest suggested that many terminal arrhythmias begin as a rapid nonsinusoidal VT.[5] These observations have been confirmed in many patients fortuitously wearing ambulatory electrocardiographic recorders at the time of sudden death.[6] Shortly after the first human implant of the automatic defibrillator, this

From the Cardiology Division, Stanford University Medical Center, Stanford, California, and Intec Systems Inc., Pittsburgh, Pennsylvania.

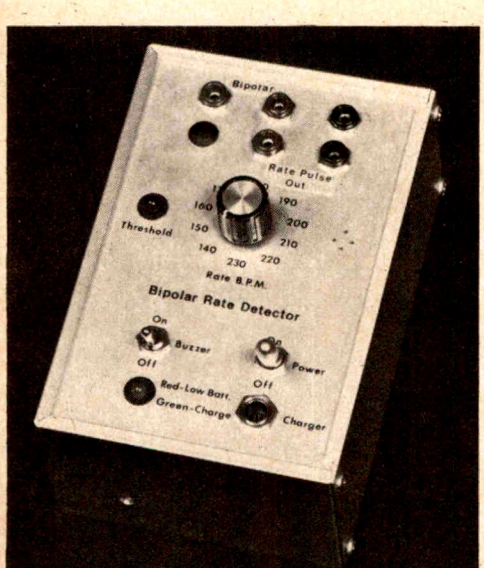
be used in some patients with nonsinusoidal VT. However, the transcardiac electrocardiographic signal ecorded from the patch and spring has a number of mitations for rate counting, including double counting f heart rate in some patients due to large amplitude P aves[7] as well as postshock ST-T abnormalities which ould cause difficulties in postshock rhythm identifiation. Furthermore, some patients with VT at rates xceeding the rate setting of the defibrillator did not ave the arrhythmia sensed because of failure of the VT satisfy the probability-density function. A local entricular bipolar electrogram was developed to proide a signal more suitable for rate detection. The lectronic sensing was specifically designed to sense the w-amplitude fragmented electrograms that occur uring VF but not to sense noise, T waves, and P waves uring sinus rhythm. The sensing system can deal with gnals of varying morphologic characteristics and mplitude, such as those occurring during episodes of olymorphic VT.

This report describes our evaluation of this sensing heme in a group of patients being studied in the ectrophysiology laboratory. It also details our clinical xperience in 9 patients who received an implanted efibrillator using local ventricular bipolar sensing and ompares the sensing to that observed in our first 5 atients who received automatic implantable defibrilators without local ventricular bipolar sensing.

Methods

Preliminary testing: Ten patients aged 53 to 72 years ndergoing 16 electrophysiologic studies for antiarrhythmic rug selection were the subjects of this part of the study. The agnosis was coronary disease in 9 and primary myocardial sease in 1.

A standard quadripolar USCI® 6Fr temporary pacing theter with 1-cm interelectrode distances was positioned the right ventricular apex. The proximal pair of electrodes ovided the bipolar input for a battery-operated bread-board



model (Fig. 1) of the new rate detection circuits. These circuits perform rate averaging, which requires longer runs of VT to satisfy the sensing criteria when the preceding sinus rhythm is slow than when it is rapid, and requires more time for sensing when there are occasional nonsensed QRS complexes. The circuit uses automatic gain control, which permits reliable detection of signals as small as approximately 0.1 mV. This bread-board model contained only the sensing circuit and did not deliver a cardioverting or defibrillating shock. With each ventricular electrogram the circuits provided an audible beep and a 180-ms square-wave output. The heart rate criterion for tachycardia detection could be preselected from 140 to 230 beats/min in increments of 10 beats/min. Once the rate of a tachycardia was consistently above the preselected rate, it was "sensed," the beep tone became continuous, and the gain of the square-wave output was manually decreased.

Electrophysiologic study was performed in the usual manner, with ventricular tachyarrhythmias induced using 1 to 3 ventricular extrastimuli in either sinus rhythm or ventricular drive. Multiple surface leads, 1 or more intracardiac leads, femoral aortic pressure, and the square wave from the bread-board rate detection circuit were displayed on a strip chart recorder. For each episode of induced VT the time and number of QRS complexes from onset of tachycardia to sensing by the rate detection circuit was recorded.

Implanted defibrillators: Rate detection circuits similar to those tested in the electrophysiology laboratory were incorporated into the automatic implantable defibrillator. This new model is the AID-B® and has been implanted in 9 patients at Stanford Medical Center. In all patients the clinical indication for implantation was drug-resistant recurrent VT or VF. All patients underwent left lateral thoracotomy for implantation of the standard apical patch electrode and a pair of Medtronic 6917A-53T screw-in electrodes for the local ventricular bipolar sensing signal. The screw-in leads were positioned in the area of healthiest appearing ventricular myocardium, generally near the anterobasal portion of the left ventricle. The superior vena caval spring electrode was placed through the left subclavian vein using the Seldinger technique. At the time of implant the unfiltered signal was recorded from local ventricular bipolar leads as well as from spring-patch transcardiac leads. VT was induced for measurement of defibrillation/cardioversion thresholds as well as for testing the AID-B unit after the generator was connected to the leads. For episodes of VT and VF induced with the AID-B generator connected to the leads, the time from onset of arrhythmia to sensing was determined. For these 9 patients the signal amplitude and quality from the local ventricular bipolar pair was compared with that of the transcardiac electrocardiographic signal. In addition, sense times for the AID-B unit with local bipolar sensing was compared with results obtained in our first 5 implants of AID® units, which used the transcardiac spring-patch system for rate detection rather than local bipolar rate sensing. All statistical comparisons were made using a 2-tailed t test for either paired or unpaired data when appropriate.

Results

Testing during electrophysiologic study: Forty-four episodes of VT were induced in the 10 patients. The rate criterion was selected to be slightly below the rate of the patient's previously documented VT and was 140 beats/min for 12 episodes, 150 beats/min for 14 episodes, 160 beats/min for 17 episodes, and 180 beats/min for 1 episode. A typical episode of VT induction and sensing by the rate detection circuit is shown in Figure

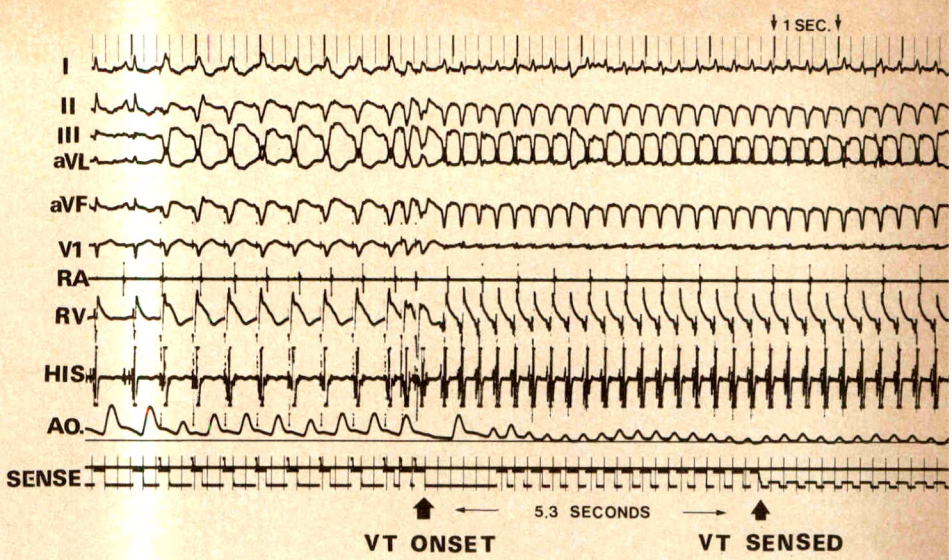


FIGURE 2. A typical episode of ventricular tachycardia (VT) induction and sensing by the rate detection circuit. Shown are surface leads I, II, III, aVL, and V_1 as well as a right atrial (RA) bipolar electrogram, a right ventricular (RV) unfiltered bipolar electrogram, electrograms recorded from the His position and systemic arterial pressure (AO). The line labeled SENSE shows the square-wave output of the rate detection circuit. VT is initiated by a pair of ventricular extrastimuli given in ventricular drive and is labeled VT ONSET. Then, 5.3 seconds later, the beeping tone of the bread-board circuits are continuous and the gain of the square-wave output decreases. This is the time at which the device sensed VT. Had a defibrillator actually been implanted, this VT sensing would have initiated a charging cycle and a shock would have been delivered approximately 7 seconds later.

implanted in these patients, sensing by the rate detection circuit would have initiated charging of the capacitors which store the defibrillation/cardioversion shock. The delay from time of arrhythmia sensing until delivery of the converting shock is 7 to 10 seconds.

Figure 3 shows the outcome in the 44 episodes of induced VT. Eleven episodes spontaneously terminated after 8 to 19 QRS complexes. Three of these episodes were sensed by the device after 11, 12, and 15 beats, or 3.5, 4, and 5 seconds, respectively. These 3 episodes would have spontaneously terminated before delivery of a converting shock (7 to 10 seconds later) had a defibrillator been in place, and an R-wave synchronous shock would have been delivered during sinus rhythm. Thirty-three episodes of VT were sustained and did not terminate until rapid pacing or external transthoracic cardioversion was performed. The average rate of the induced tachycardia and the number of QRS complexes and time from onset until sensing is summarized in Table I. All 22 episodes of VT with rates above the preselected setting on the bread-board circuit were sensed after an average of 5.1 ± 1.8 seconds. Two episodes of induced VT with rates virtually identical to the preselected rate were sensed after 19 and 21.5 seconds. Nine episodes of induced VT were below the cutoff rate selected and none were sensed as a rhythm to be shocked despite persistence for several minutes or longer in most patients. Neither the time elapsed from onset of VT until sensing nor the number of QRS complexes elapsed before sensing was clearly a function of the underlying rate of the VT (Fig. 4 and 5).

In addition to the 44 episodes of VT induced during ventricular drive or sinus rhythm, 10 VTs of different morphologic characteristics and rate and 6 episodes of VF were induced during attempts at tachycardia termination by pacing. All 16 episodes were sensed by the rate detection circuit.

Clinical experience: Fourteen patients have had automatic defibrillators implanted at Stanford Medical Center. The first 5 patients received AID devices using arrhythmia detection based on the probability-density function and heart rate derived from the transcardiac spring-patch electrode pair. The last 9 patients received AID-B devices using a local ventricular bipolar rate detection circuit similar to the one tested in the electrophysiology laboratory. The initial 5 patients had 16 episodes of VT or VF induced at implant or predischarge electrophysiologic study. Two episodes were not sensed because of failure to satisfy the probability density function. The sensing time for the 14 other episodes was 12.2 ± 7.1 seconds (range 5.6 to 27.6). The 9 patients who received the AID-B devices with the new local ventricular bipolar sensing circuit had a total of 29 episodes of VT or VF induced at the time of implant or

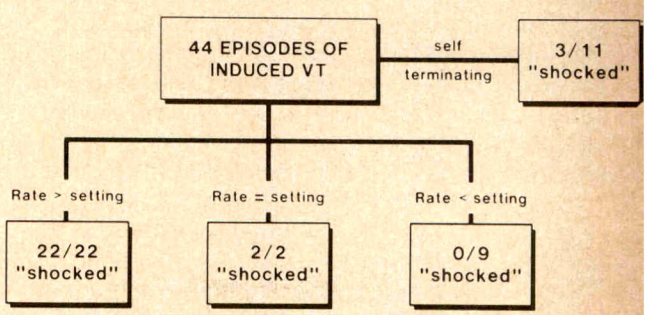

FIGURE 3. Outcome in 44 episodes of induced ventricular tachycardia (VT).

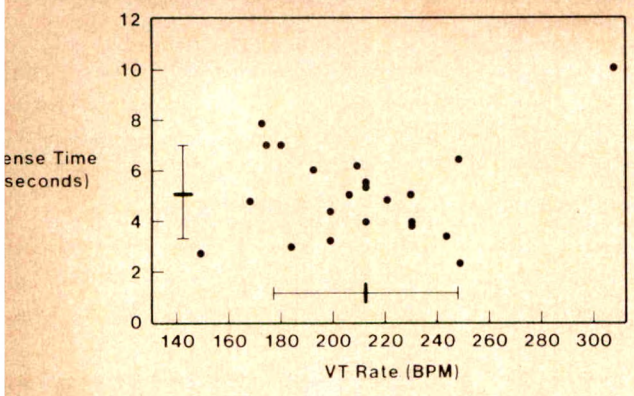
TABLE I Summary of Sensing Data for 44 Episodes of Ventricular Tachycardia (VT)

	Rate >Setting	Rate = Setting	Rate <Setting
Number of episodes	22	2	9
VT rate	212 ± 36	140,150	130 ± 15.6
QRS's to sensing	18 ± 8.0	50,51	—
Time to sensing	5.1 ± 1.8	21.5,19	



GURE 4. Time (in seconds) from the onset of ventricular tachycardia T) until it was sensed by the rate detection circuits as a function of e ventricular tachycardia rate.

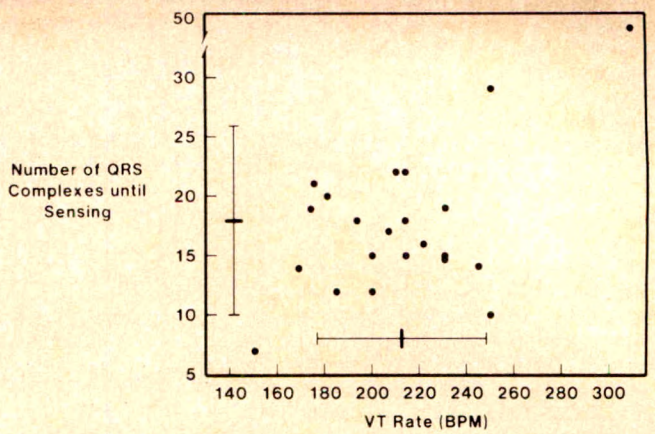


FIGURE 5. The number of QRS complexes from the onset of ventricular tachycardia (VT) until sensing by the rate detection circuits as a function of the ventricular tachycardia rate.

uring postoperative electrophysiologic study. All 29 pisodes were appropriately sensed with an average ensing time of 5.5 ± 1.4 seconds (range 3.4 to 7.8). The atients receiving the AID-B automatic implantable efibrillator with local bipolar sensing had more uni- orm and shorter ($p = 0.01$) sensing times than did pa- ents receiving AID units without this type of ensing.

For patients receiving the AID-B defibrillators, it was ossible to compare the signal amplitude and quality f the local bipolar electrogram to that of the simulta- eously recorded transcardiac spring-patch signal uring both sinus rhythm and induced ventricular ar- ıythmias. In sinus rhythm the average amplitude of ıe unfiltered local bipolar electrogram was consider- bly greater than that of the spring-patch (10.4 ± 7.15 ıV versus 4.1 ± 3.1 mV). During 25 episodes of induced T the average local ventricular bipolar signal ampli- ıde was 9.9 ± 10.4 mV and the amplitude across the ring-patch lead was 5.2 ± 3.0 mV. Six of the 9 patients ad considerably larger electrograms during VT in the ipolar lead compared with the spring-patch lead, in 1 atient signal amplitudes were approximately identical nd in 2 patients electrogram amplitude was greater in ıe spring-patch lead. There was considerable post- ıock signal distortion in the spring-patch electrocar- iographic signal due to S-T segment changes. Post- ıock signal distortion was minimal in the local bipolar ntricular electrogram.

The opportunity to directly compare the sensing time f the old AID system to the sensing time of the new ipolar rate detection system occurred during an elec- ophysiologic study in 1 patient who had an automatic nplantable defibrillator using transcardiac rate de- ction rather than the new local ventricular bipolar rcuit. The new rate detection circuit sensed the ıythm approximately 3 seconds earlier than did the nplanted device (Fig. 6).

In 13 of the 14 patients, all sensed episodes of VT or F were terminated with a single shock from the auto- atic implanted defibrillator. In 1 patient the energy the shocks delivered from the spring-patch electrode stem was insufficient to consistently terminate VF. In this patient, the use of a pair of patch leads for delivering the shocks resulted in termination of 7 consecutive episodes of induced VF, each with a single shock. The average energy delivered from the devices implanted in these 14 patients was 24.9 ± 2.4 joules (range 23 to 30).

Discussion

Reliable sensing of VT and VF is not a simple task. Sensing circuits must detect low-amplitude fragmented electrograms that may occur during VF, but must not sense noise during sinus rhythm. There must be short refractory periods to detect rapid ventricular rates even though these short refractory periods increase the likelihood of inappropriate sensing of T waves and noise. These circuits must also be able to detect arrhythmias associated with a rapidly changing electrocardiographic morphology and amplitude such as occurs during polymorphic VT or torsades de pointes.

Even more difficult than detecting VT and VF is distinguishing between supraventricular tachycardia (SVT) with aberration and VT. On the basis of surface electrocardiograms, this distinction is often difficult and sometimes impossible. Fully morphology-dependent arrhythmia detection systems such as the probability-density function will not distinguish all SVTs from VTs, because some patients with preexisting bundle branch block will have wider and more abnormal QRS complexes during SVT than during episodes of VT. Furthermore, many patients with recurrent sustained VT have markedly different morphologic characteristics from 1 episode of tachycardia to the next. The availability of atrial and ventricular electrograms for arrhythmia definition cannot reliably distinguish these 2 rhythms, because virtually any relation between atrial and ventricular activation may occur. Typical examples include complete atrioventricular dissociation, 1 to 1 relations between atria and ventricles with atrial electrograms simultaneous with, after, or preceding each ventricular electrogram and a spectrum of anterograde and retrograde block. Furthermore, atrioventricular

relations may differ in the same patient from 1 episode to the next depending on autonomic tone, rate of tachycardia, and presence or absence of antiarrhythmic therapy. Detection schemes relying on monitoring of arterial pressure to define rhythms that should be shocked are not fully reliable either, because many patients with poor left ventricular function will decompensate as much from SVT as from VT, whereas patients with reasonably good ventricular function may tolerate rapid VTs. Currently, we cannot envision a practical system for reliably distinguishing all SVT, especially those with aberrant conduction from VT.

The rate detection circuits evaluated in the present study never failed to sense an episode of VT whose rate exceeded the preselected rate cutoff. The rate averaging and automatic gain control features also provide reliable detection of polymorphic VT and VF. The availability of these rate detection circuits markedly expands the number of patients for whom an automatic implanted defibrillator may provide life-saving therapy from a relatively small group with sinusoidal VT or VF to the much larger group with recurrent sustained VT. In over 50 hours of evaluation in the electrophysiology laboratory and 40 patient-months of follow-up, this system has not been documented to have inappropriately sensed T waves or noise.

Detection of ventricular tachyarrhythmias based on rate alone is not a perfect method. Any sinus or other tachycardia will satisfy the detection scheme and clinically inappropriate shocks may be delivered. Furthermore, selection of an appropriate rate for each patient can be difficult. For many patients there may be overlap in the maximum sinus rates achieved during activity or emotional stress and the rates of ventricular tachyarrhythmias, especially in patients receiving antiarrhythmic therapy. Furthermore, the rate of VT may vary from 1 episode to the next or when antiarrhythmic drug therapy changes. Nonetheless, it remains possible to select for most patients a rate cutoff criterion which is not frequently achieved by their sinus mecha-

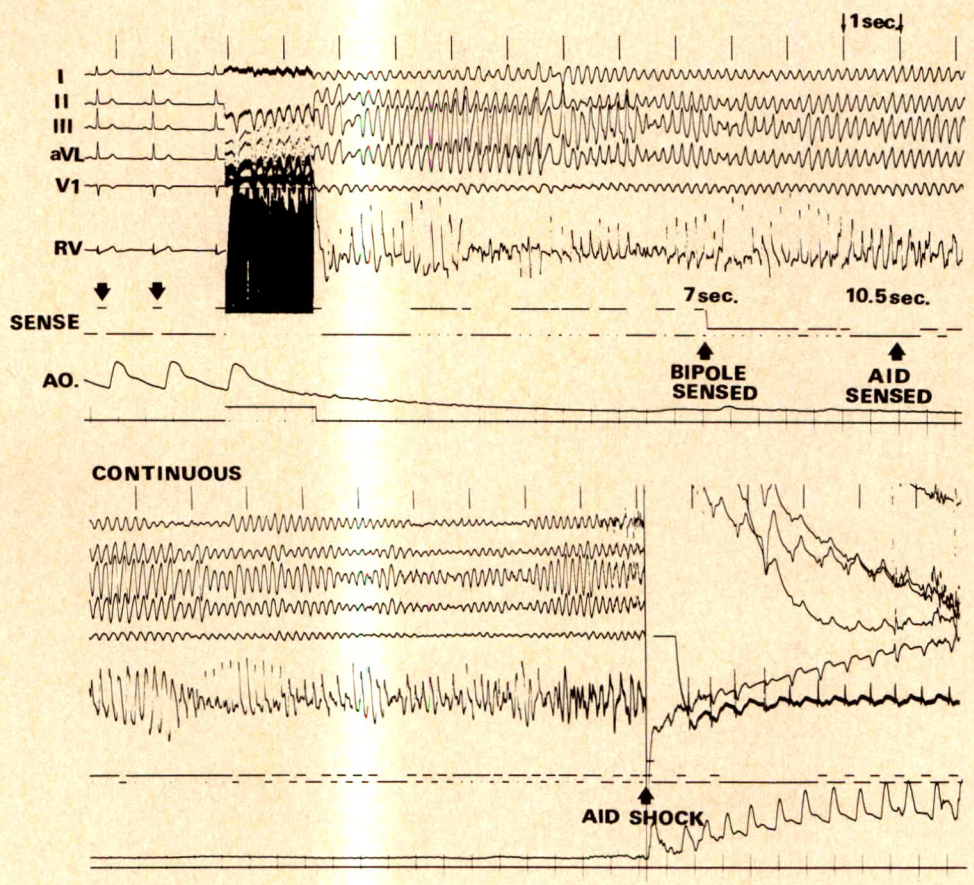

FIGURE 6. Comparison of the sensing time of the new bipolar rate detection circuits and the old arrhythmia detection circuits using the spring-patch electrode. These recordings were made at the time of electrophysiologic study in a patient with a previously implanted automatic defibrillator which used spring-patch sensing. At the time of electrophysiologic study, a right ventricular bipolar signal provided input for the bread-board circuit, so that the sensing time of the new bipolar circuits could be directly compared with that of the previous automatic implanted defibrillator (AID). Shown in the **upper** and **lower panels** is a continuous electrocardiographic strip showing surface leads I, II, III, aVL, and V_1 as well as a right ventricular electrogram (RV), the square-wave sensing output of the bread-board circuit (SENSE), and the systemic arterial pressure (AO). During sinus rhythm ventricular fibrillation is induced with a brief burst of pacing at cycle length 10. Most of the right ventricular electrograms during ventricular fibrillation are sensed by the bipolar circuit as indicated by the square-wave output. After 7 seconds of ventricular fibrillation the bipolar circuits sensed the arrhythmia, the beeping tone became continuous, and the gain of the square-wave output was decreased. It was not until 3.5 seconds later (10.5 seconds after the onset of ventricular fibrillation) that the AID using spring-patch sensing sensed this arrhythmia. The AID automatically began charging and delivered a shock approximately 11 seconds later, which terminated the ventricular fibrillation.

ism and which is below that of the VT one desires to erminate. The rate detection circuits may also be used n conjunction with a morphology-dependent criteria, uch as the probability-density function, to minimize he possibility of delivery of shocks during sinus or other arrow-QRS SVT. However, the addition of a morphology-dependent criterion is done at the expense of ncreasing the likelihood that some VTs will not be ecognized by the system.

Selection of the appropriate rate cutoff and incorporation of a sensitivity setting for probability density unction must be made on an individual patient basis. The availability of external programmability in the near uture will enhance the ability to customize the implanted defibrillator to individual patient's needs. To late the delivery of synchronized shocks during sinus hythm has not been associated with significant morality or morbidity except for discomfort. It has been our philosophy to select devices that are unlikely to fail to letect a serious ventricular tachyarrhythmia but that may occasionally deliver a shock for a sinus or other SVT. Further refinements in programmability of devices and detection schemes should improve the ratio of clinically appropriate to inappropriate shocks.

Effects of Oral Diltiazem in Paroxysmal Supraventricular Tachycardia

SAN-JOU YEH, MD, HWAI-CHENG KOU, MD, FUN-CHUNG LIN, MD, JUI-SUNG HUNG, MD, and DELON WU, MD

Electrophysiologic studies were performed before and 2 hours after the oral administration of 270 mg of diltiazem in 3 divided doses at 8-hour intervals in 36 patients with paroxysmal supraventricular tachycardia (SVT). Before diltiazem, all 36 patients had induction of sustained SVT: 24 with atrioventricular (AV) reentrance incorporating an accessory pathway (Group 1) and 12 with AV nodal reentrance (Group 2). After diltiazem, 20 patients in Group 1 lost the ability to induce or sustain SVT because of increased anterograde normal pathway refractoriness in 19 patients and increased retrograde accessory pathway refractoriness in 1. Eight patients in Group 2 could no longer induce or sustain SVT because of increased anterograde slow pathway refractoriness in 2 patients and increased retrograde fast pathway refractoriness in 6. Diltiazem concentration in the blood, measured in 29 patients, was 156 ± 75 ng/ml (mean ± standard deviation). Fifteen patients, 2 with and 13 without induction of sustained SVT after diltiazem, were discharged on the same dosage of diltiazem and followed up 5 ± 3 months. The former 2 patients had attacks of sustained SVT, whereas the latter 13 have been free of sustained SVT. In conclusion, oral diltiazem prevents induction and sustenance of paroxysmal SVT in most patients and may be used as an alternative agent for the prophylaxis of SVT.

Diltiazem is 1 of the more promising calcium antagonists proved effective in the management of angina pectoris. Similar to verapamil, diltiazem is electrophysiologically potent, capable of depressing atrioventricular (AV) nodal conduction.[1–4] Limited clinical data have shown that intravenous diltiazem terminates paroxysmal supraventricular tachycardia (SVT) and slows the ventricular rate during atrial fibrillation.[5–7] However, systematic studies on the electrophysiologic effects of diltiazem in patients with paroxysmal SVT are lacking. In this study we evaluated the effects of oral diltiazem on the induction and sustenance of paroxysmal SVT in a large group of patients.

Methods

Patients: The study population consisted of 36 patients, 21 male and 15 female, aged 17 to 69 years (mean ± standard deviation 37 ± 15). All study patients had electrocardiographic documentation of recurrent SVT, which could be electrophysiologically induced on the day of the control study. Of the 36 patients, 33 had no demonstrable organic heart disease, and 3 had a history of systemic hypertension.

Electrophysiologic studies: Each patient gave written informed consent. Electrophysiologic studies were performed in the supine, postabsorptive, and nonsedated state. Cardioactive drugs were discontinued at least 5 half-lives before the study. A #7 quadripolar electrocatheter was introduced percutaneously into the right femoral vein and positioned across the tricuspid valve; the proximal 2 electrodes were used for His bundle recording, whereas the distal 2 electrodes were used for right ventricular pacing. A #7 hexapolar electrodecatheter was introduced through cutdown to the right antecubital vein and advanced to the coronary sinus. In this position, the proximal 4 electrodes were located against the lateral wall of the high right atrium near the junction of the superior vena cava. The distal 2 electrodes were used to record the left atrial electrogram from the coronary sinus, the middle 2 to record the high right atrial electrogram, and the proximal 2 for right atrial pacing. Multiple surface and intracardiac electrograms were simultaneously displayed and recorded on a multichannel oscilloscopic photographic recorder (Electronics for Medicine VR-16, White Plains, New York) at paper speeds of 100, 150, and 250 mm/s, and at a filter setting between 30 and 500 Hz. Stimuli 2 ms in duration and approximately twice the diastolic threshold were delivered by a pro-

grammable digital stimulator (DTU PC 100, Bloom and Associates, Narberth, Pennsylvania).

The study protocol included (1) incremental atrial pacing to the atrial paced cycle length that induced AV block, (2) atrial extrastimulus testing (A_1 A_2 testing) at sinus and a driven cycle length of 600 or 500 ms, and double extrastimulus testing (A_1 A_2 A_3 testing) in those patients in whom A_1 A_2 failed to induce either echo beats or SVT, (3) incremental ventricular pacing to the paced cycle length that induced ventriculoatrial (VA) block, (4) ventricular extrastimulus testing (V_1 V_2 testing) at driven cycle lengths of 600 or 500 or both, (5) mapping of the atrial activation sequence during induced SVT, and (6) delivery of a ventricular extrastimulus during induced SVT. At the completion of the control study, the tip of the hexapolar catheter was repositioned at the right ventricular apex, and the proximal 4 electrodes were maintained in the initial atrial positions. The hexapolar catheter was then secured for subsequent electrophysiologic studies. The quadripolar electrocatheter was removed. The patient was then given oral diltiazem (release-controlled tablet, Tanabe Seiyaku Co, LTD, Osaka, Japan), 90 mg every 8 hours, and the electrophysiologic studies were repeated 2 hours after the third dose of diltiazem. In 29 patients blood samples were taken at the time of the electrophysiologic studies to measure plasma diltiazem concentration using thin-layer chromatography[8,9] (measured by Tanabe Seiyaku Co, LTD, Osaka, Japan).

Electrophysiologic definitions: Anterograde properties were evaluated by noting the longest atrial paced cycle length that induced 2° AV block and by measuring the effective refractory period of the AV conducting system. Retrograde properties were evaluated by noting the longest ventricular paced cycle length that induced VA block and by measuring the effective refractory period of the VA conduction system. For comparison, pre- and postdiltiazem values of anterograde properties were measured from the high right atrial electrogram at identical driven cycle lengths. Conduction intervals and refractory periods were defined and measured as previously described.[10,11] The incorporation of an accessory pathway for retrograde conduction during induced SVT was suggested by (1) an abnormal atrial activation sequence during induced SVT, (2) an increment in VA conduction time with the development of bundle branch block ipsilateral to the accessory pathway during induced tachycardia, and (3) the ability to capture the atrium by a critically timed ventricular extrastimulus given during SVT when the His bundle was noted to be refractory.[10–16] The diagnosis of AV nodal reentrant tachycardia was made using previously described criteria, and the possibility of AV and atrial reentrant tachycardia was excluded.[11–17]

Sustained SVT is defined as an episode of induced SVT >2 minutes in duration which requires termination with electrical stimulation. Nonsustained SVT after diltiazem is defined as all episodes of induced SVT that terminate spontaneously within 10 seconds. Anterograde weak-link of the reentrant circuit refers to termination of either echoes or SVT that occurs with an atrial response that is not followed by a ventricular response. Retrograde weak-link of the reentrant circuit refers either to termination of echoes or SVT that occurs with a ventricular response that is not followed by an atrial response or to the achievement of an HRA-V interval that is longer than the observed control critical AV interval without the induction of AV or AV nodal reentrant echoes.

Data analysis and follow-up: Data were expressed as mean ± standard deviation and were analyzed with the paired Student t test. Fifteen patients were discharged on oral diltiazem, 90 mg every 8 hours, and were followed up in the clinic for 5 ± 3 months.

Results

Of the 36 patients, 24 had AV reentrant tachycardia incorporating an accessory pathway conducting retrogradely (Group 1) and 12 of the 36 patients had AV nodal reentrant tachycardia using a slow pathway for anterograde and a fast pathway for retrograde conduction (Group 2). Ten of the former 24 patients had ventricular preexcitation, whereas 14 had a concealed accessory pathway.

Effects on AV reentrant tachycardia (Table I, Cases 1 to 24; Fig. 1 and 2): In all 24 patients, sustained SVT could be induced before diltiazem. After diltiazem, sustained SVT could be induced in only 4 patients (Cases 1 to 4), nonsustained SVT occurred in 3 patients (Cases 5 to 7) (Fig. 2), a single AV reentrant atrial echo occurred in 12 patients (Cases 8 to 19), (Fig. 1), and neither SVT nor an echo could be induced in 5 patients (Cases 20 to 24). Of the 15 patients in whom either nonsustained SVT or a single AV reentrant atrial echo could be induced after diltiazem, the weak link occurred in the anterograde direction in 14 patients (Fig. 1D) and in the retrograde direction in 1 patient (Case 7) (Fig. 2D). In the 5 patients in whom neither SVT nor echo could be induced after diltiazem, the factor limiting induction was either failure to achieve a critical AV interval (Case 20) or failure of normal pathway conduction due to a longer refractoriness of the normal pathway than of the accessory pathway (Cases 21 to 24).

The cycle length of the SVT could be compared before and after diltiazem only in 7 patients (Cases 1 to 7) in whom SVT could be induced after diltiazem. In these 7 patients, the cycle length of the SVT was 349 ± 61 ms (range 290 to 450) before and 399 ± 51 ms (range 310 to 445) after diltiazem (difference not significant [NS]). The cycle length of the SVT lengthened in 6 patients and shortened in 1. The changes in cycle length of the SVT reflected changes in the AV interval, because the VA interval remained unchanged after diltiazem.

The longest atrial paced cycle length that induced 2° AV block could be compared in 20 patients (Cases 1 to 5, 8, 10 to 23) and increased from 301 ± 67 ms (range <240 to 400) before to 397 ± 67 ms (range ≥260 to 500) after diltiazem ($p < 0.001$) (Fig. 1A and 1C). Measurement of the anterograde effective refractory period was frequently impossible after diltiazem because of the occurrence of echoes or second-degree (2°) AV block, or both, at the basic driven cycle length (Fig. 1C). The anterograde effective refractory period of the normal pathway could be compared in 14 patients (Cases 3, 4, 7, 8, 10 to 12, 15, 16, and 18 to 22), and increased from 255 ± 39 ms (range <160 to 300) before diltiazem to 319 ± 47 ms (range 220 to 370) after diltiazem ($p < 0.01$). The effects of diltiazem on the anterograde properties of the accessory pathway were variable. The longest atrial paced cycle length that induced block in the accessory pathway was compared in 7 patients (Cases 7, 8, 10, 11, and 21 to 23). It was 420 ± 164 ms (range <260 to 690) before and 397 ± 150 ms (range 260 to >730) after diltiazem (p = NS). The anterograde effective refractory period of the accessory pathway was compared in 7 patients (Cases 7, 9, 10, and 21 to 24) and was

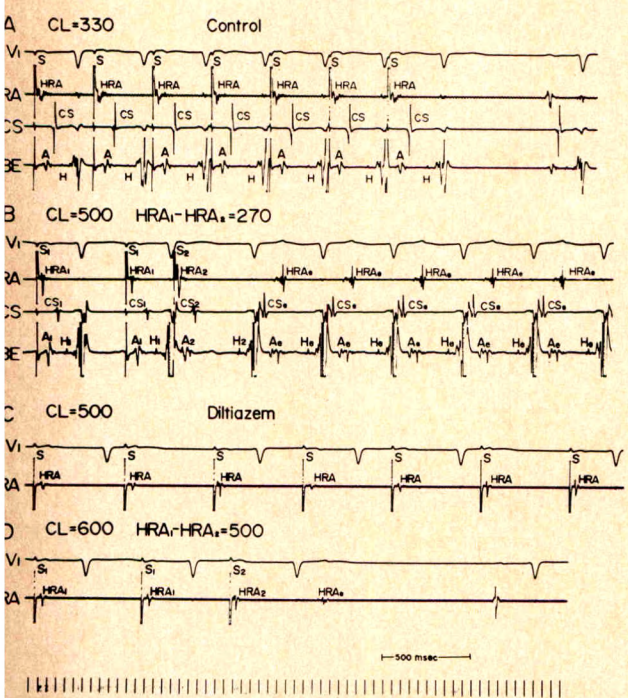
Ant = anterograde; C = control; CL = cycle length; CL-APB = the longest atrial paced cycle length that induced block in the accessory pathway; CL-AVB = the longest atrial paced cycle length that induced block in the normal pathway; CL-VAB = the longest ventricular paced cycle length that induced ventriculoatrial block; D = diltiazem; ERP-AP = the effective refractory period of the accessory pathway; ERP-At = the atrial effective refractory period; ERP-AVCS = the effective refractory period of the atrioventricular conducting system (normal pathway); ERP-VACS = the effective refractory period of the ventriculoatrial conducting system; ERP-Vt = the ventricular effective refractory period; 0 = no induction of paroxysmal supraventricular tachycardia (PVST), unable to sustain PSVT or no weak link; Ret = retrograde; + = induction of PSVT or ability to sustain PSVT; — = data not generated.

86 ± 60 ms (range 240 to 420) before and 289 ± 37 ms ange <240 to 340) after diltiazem (p = NS).

The longest ventricular paced cycle length that inuced 2° VA block (in the accessory pathway) could be ompared in 9 patients (Cases 7, 12, 13, 15, 17, 19, 20, 22, nd 23) and was 279 ± 12 ms (range <280 to 300) before nd 302 ± 17 ms (range <280 to 330) after diltiazem (p 0.02) (Fig. 2A and 2C). The retrograde effective reactory period of the VA conducting system (the accessory pathway) could be compared in 18 patients Cases 1, 3, 4, 6 to 8, 11 to 20, 22, and 23) and was 248 ± 4 ms (range <200 to 370) before and 293 ± 29 ms ange 240 to 340) after diltiazem (p <0.001) (Fig. 2B and E).

Effects on AV nodal reentrant tachycardia Table II, Cases 25 to 36; Fig. 3 and 4): In all 12 paents, sustained SVT could be induced before diltiazem. After diltiazem, sustained SVT could be induced in 4 patients (Cases 25 to 28), nonsustained SVT in 2 patients (Cases 29 and 30) (Fig. 3), a single AV nodal reentrant echo in 2 patients (Cases 31 and 32), and neither SVT nor an echo could be induced in 4 patients (Cases 33 to 36) (Fig. 4). In patients in whom nonsustained SVT or a single echo could be induced, the weak link occurred in the anterograde direction in 2 patients (Cases 29 and 32) (Fig. 3B), and the retrograde direction in 2 patients (Cases 30 and 31). In the 4 patients in whom neither SVT nor an echo could be induced, the weak link occurred in the retrograde direction. The cycle length of the SVT, which could be compared in 5 patients, lengthened in 3 patients (Cases 26, 28, and 30), remained unchanged in 1 patient (Case 25), and shortened in 1 patient (Case 27). Overall, the cycle length was



GURE 1. Recordings from Case 17 showing the induction of a single rioventricular (AV) reentrant echo after diltiazem and the effects of tiazem on anterograde AV conduction. Electrocardiographic V_1, high ght atrial electrogram (HRA), left atrial electrogram recorded from the ronary sinus (CS), and His bundle electrogram (HBE) are shown. HRA, S, A, and H represent, respectively, the high right atrial, left atrial, low ptal right atrial, and His bundle responses to the driven stimulus (S). HRA_e, CS_e, A_e, and H_e represent, respectively, high right atrial, left atrial, w septal right atrial, and His bundle responses during induced reentrant hoes or tachycardia, or both. HRA_1, A_1, and H_1 represent, respecely, high right atrial, low septal right atrial, and His bundle responses the basic driven stimulus (S_1). HRA_2, A_2, and H_2 represent, respecely, high right atrial, low septal right atrial, and His bundle responses the extrastimulus (S_2). The paper speed is 100 mm/s. **A,** 1:1 AV nduction at an atrial paced cycle length of 330 ms before diltiazem. the induction of sustained AV reentrant supraventricular tachycardia th an atrial extrastimulus before diltiazem. The atrial driven cycle ngth was 500 ms, and the coupling interval was 270 ms. **C,** 2° AV ock at an atrial paced length of 500 ms after diltiazem. **D,** the induction a single echo with an atrial extastimulus after diltiazem. The atrial ven cycle length was 600 ms and the coupling interval was 500 ms. e echo (HRA_e) was not followed by a QRS complex, suggesting an terograde weak link.

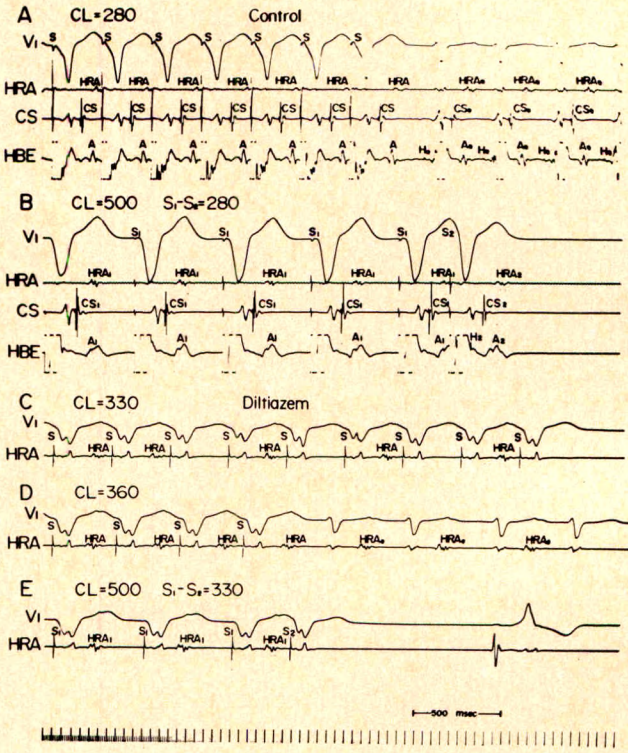


FIGURE 2. Recordings in Case 7 showing the induction of nonsustained atrioventricular (AV) reentrant supraventricular tachycardia (SVT) after diltiazem and the effects of diltiazem on retrograde accessory pathway conduction. **A,** the induction of sustained SVT after termination of rapid ventricular pacing at a paced cycle length of 280 ms before diltiazem. Note 1:1 ventriculoatrial (VA) conduction during ventricular pacing. **B,** the conduction of the ventricular extrastimulus to the atria through a left-sided accessory pathway at a coupling interval of 280 ms and a basic driven cycle length of 500 ms before diltiazem. CS_2 was activated earlier than both A_2 and HRA_2. **C,** the occurrence of 2° VA block after diltiazem at a ventricular paced cycle length of 330 ms. **D,** the induction of nonsustained SVT after diltiazem after the termination of rapid ventricular pacing at a paced cycle length of 360 ms. Termination of SVT occurred when the QRS complex was not followed by an atrial response, suggesting a retrograde weak link. **E,** the block of the ventricular extrastimulus to the atria after diltiazem at a coupling interval of 330 ms and a ventricular driven cycle length of 500 ms. Thus, the effective refractory period of the VA conducting system (the accessory pathway) was increased from <280 to 330 ms after diltiazem. Other abbreviations as in Figure 1.

IGURE 3. Recordings in Case 29 showing the induction of nonsustained rioventricular (AV) nodal reentrant echoes after diltiazem and the ffects of diltiazem on anterograde slow-pathway conduction. **A,** the duction of sustained supraventricular tachycardia (SVT) after termiation of rapid atrial pacing at a paced cycle length of 330 ms before ltiazem. Note 1:1 slow pathway conduction during atrial pacing. **B,** e occurrence of 2° AV block at an atrial paced cycle length of 430 s, reflecting an increased anterograde slow pathway refractoriness ter diltiazem. **C,** the induction of nonsustained echoes with an atrial xtrastimulus after diltiazem. The atrial driven cycle length was 500 s and the coupling interval was 260 ms. The echoes were terminated ith HRA_e not being followed by a QRS complex, suggesting an anrograde weak link. Other abbreviations as in Figure 1.

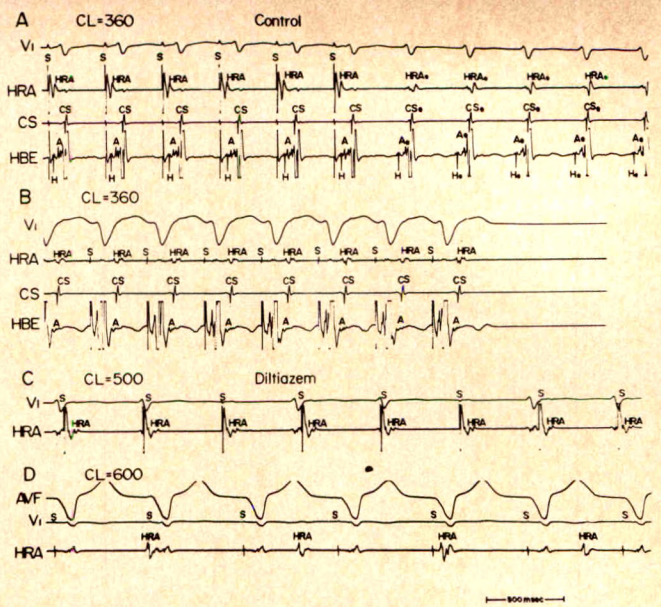

FIGURE 4. Recordings in Case 33 showing effects of diltiazem on the anterograde slow pathway and the retrograde fast pathway conduction. **A,** the induction of sustained atrioventricular (AV) nodal reentrant supraventricular tachycardia (SVT) after termination of rapid atrial pacing at a paced cycle length of 360 ms before diltiazem. Note 1:1 slow pathway conduction during rapid atrial pacing. **B,** 1:1 ventriculoatrial (VA) conduction during rapid ventricular pacing at a paced cycle length of 360 ms before diltiazem. **C,** 2° AV block at an atrial paced cycle length of 500 ms after diltiazem, reflecting an increased anterograde slow pathway refractoriness. **D,** no VA conduction at a ventricular paced cycle length of 600 ms after diltiazem, suggesting an increased retrograde fast pathway refractoriness. Other abbreviations as in Figure 1.

97 ± 60 ms (range 285 to 450) before and 429 ± 79 ms range 340 to 570) after diltiazem (p = NS).

The longest atrial paced cycle length that induced 2° V block could be compared in all 12 patients and increased from 326 ± 42 ms (range <280 to 400) to 440 ± 5 ms (range 330 to 545) after diltiazem (p <0.001) (Figs. A and 3B, 4A and 4C). The anterograde effective refractory period of the AV conducting system (reflecting that f the slow pathway) could be compared in only 4 patients (Cases 25, 27, 29, and 34) and was decreased in 1 atient (Case 25) and increased in 3 (Cases 27, 29, and 4). In 5 patients (Cases 28, 32, 33, 34, and 35), the longest atrial paced cycle length that induced AV block fter diltiazem was longer than the control basic driven ycle length.

The longest ventricular paced cycle length that induced 2° VA block could be compared before and after iltiazem in 9 patients (Cases 25 to 32 and 35), and increased from 303 ± 25 ms (range <280 to 360) to 382 ± 0 ms (range <280 to 545) after diltiazem (p <0.05). In he remaining 3 patients (Cases 33 to 35), no VA conduction was noted after diltiazem (Fig. 4B and 4D). The ffective refractory period of the VA conducting system ould be compared in 4 patients (Cases 29 to 32) and was ncreased in all 4.

Other observations: On the whole, the sinus cycle ength lengthened from 694 ± 104 to 779 ± 145 ms after iltiazem (p <0.001). The systolic pressure decreased om 131 ± 22 to 121 ± 16 mm Hg after diltiazem (p 0.05), whereas the diastolic pressure remained unhanged and was 85 ± 14 before and 80 ± 13 mm Hg after diltiazem (p = NS). The atrial effective refractory period increased from 211 ± 39 to 239 ± 35 ms after diltiazem (p <0.001). The ventricular effective refractory period was 219 ± 31 before and 221 ± 17 ms after diltiazem (p = NS).

Plasma diltiazem concentration was measured in 29 patients and was 156 ± 75 ng/ml (range 24 to 320). There was no difference in drug level among those patients with or without induction of sustained SVT.

Follow-up data: Fifteen patients were discharged on the same dosage of oral diltiazem and followed up in the clinic 5 ± 3 months. Of the 2 patients (Cases 25 and 26) in whom sustained SVT could be induced after diltiazem, both experienced 3 episodes of sustained SVT that required hospital visits for termination during the follow-up period. Of the 13 patients (Cases 8, 9, 12, 15, 16, 22 to 26, 33 to 35, and 39) in whom sustained SVT could not be electrically induced after diltiazem, only 1 patient (Case 22) experienced palpitations (4 episodes) during the follow-up period. The frequency of SVT in these 13 patients ranged from 1 to 4 attacks/month (mean 1.7/month) before diltiazem therapy. All 15 patients tolerated the medication well and experienced no major side effects.

Discussion

Slow-channel antagonists, such as verapamil, diltiazem, and nifedipine, are effective antianginal agents,

particularly in treating the vasospastic type of angina pectoris. Verapamil is also effective in controlling tachyarrhythmias involving the AV node.[18–22] Microelectrophysiologic studies have shown that diltiazem at a therapeutic concentration decreases the action potential plateau and shortens the action potential duration in both ventricular muscles and Purkinje fibers without significantly affecting the maximum upstroke velocity and the resting membrane potential.[23,24] In clinical and animal studies, diltiazem depresses AV nodal function with prolongation of AV nodal conduction time and both the functional and the effective refractory periods.[1–4] It reduces the sinus rate, but has no significant effects on the atria, the His-Purkinje system, and the ventricles. Limited clinical studies have shown that intravenous diltiazem terminates paroxysmal SVT and slows the ventricular rate in patients with atrial fibrillation.[5–7] The elimination half-life of intravenous diltiazem was shown to be 1.9 hours.[8,9,25] After oral administration of the release-controlled tablet, the peak plasma concentration is achieved within 3 to 5 hours, and the elimination half-life is approximately 4.5 hours.[9,25]

The findings of this study on oral diltiazem in patients with AV reentrant tachycardia showed that diltiazem depressed anterograde normal pathway conduction (AV node) and lengthened the AV nodal conduction time. However, slowing the AV nodal conduction time did not negate the beneficial effect of prolonging the AV nodal effective refractory period in most patients. Moreover, the AV node was also depressed in such a way that an appropriate AV nodal delay (in patients without preexcitation) or the normal pathway conduction (in patients with preexcitation) could not be achieved, so that echoes and tachycardia were not induced after diltiazem. These observations are consistent with the previous observations of Wakasa et al[5] and Rozanski et al.[6] Although diltiazem had no significant effect on anterograde accessory pathway conduction, it had a mild depressant effect on retrograde accessory pathway conduction, as suggested by the prolongation of both the longest ventricular paced cycle length that induced VA block and the effective refractory period of the VA conducting system. The significance of this latter finding requires further clarification.

In patients with AV nodal reentrant tachycardia, diltiazem depressed anterograde conduction (reflecting the slow-pathway conduction) as suggested by prolongation of the longest atrial paced cycle length that induced AV block. It also depressed retrograde conduction (reflecting the fast-pathway conduction) as suggested by prolongation of the longest ventricular paced cycle length that induced VA block. Wakasa et al[5] showed that the AV nodal conduction curve became continuous after diltiazem in 3 of 5 patients with discontinuous AV nodal conduction curves, suggesting increased anterograde slow pathway refractoriness. Rozanski et al[6] reported termination of tachycardia in 4 patients with AV nodal reentrant tachycardia occurring in the anterograde direction after intravenous diltiazem, suggesting increased anterograde pathway refractoriness. They also demonstrated a depressant effect of diltiazem on retrograde pathway conduction as assessed by ventricular or programmed stimulation. Studies of procainamide, quinidine, and disopyramide have shown that type I antiarrhythmic agents have a specific depressant effect on the retrograde fast AV nodal pathway.[26–28] The present study further suggests that the retrograde AV nodal pathway (the fast pathway) is subject to the influence of slow-channel antagonists. These findings imply that the retrograde fast AV nodal pathway may possess tissues that have the characteristics of both fast- and slow-channel responses.

Oral diltiazem caused a minor but significant lengthening of the sinus cycle length and a mild reduction in systolic pressure. The atrial effective refractory period increased slightly but significantly. This latter finding might be related in part to the observed depressant effect of diltiazem on retrograde accessory pathway conduction, as the measurement of the retrograde accessory pathway conduction with ventricular or programmed stimulation was dependent on the atrial response. Nevertheless, we could not exclude the possibility of an error in the measurement of the atrial effective refractory period resulting from poor contact of the catheter with the atrial wall.

Our follow-up data support the hypothesis that oral diltiazem is effective in preventing the recurrence of paroxysmal SVT and that electrophysiologic study may predict subsequent clinical responses. Our studies were performed 2 hours after only 3 doses of diltiazem. A steady-state drug level might not have been achieved in some patients. Perhaps the long-term effects of diltiazem on SVT are better than our studies suggest.

Effect of Procainamide on Dispersion of Ventricular Refractoriness

JAY A. SHECHTER, MD, RUTH CAINE, RN, TED FRIEHLING, MD, PETER R. KOWEY, MD, and TOBY R. ENGEL, MD

Ventricular arrhythmias after Q-T prolongation by drugs could result from a nonhomogeneous increase in refractoriness (dispersion). Dispersion of effective refractory periods (ERP) was measured before and after infusion of 1 g of procainamide using twice-threshold extrastimuli applied in sinus rhythm and with 500 ms ventricular drive cycle length at 3 right ventricular sites (2 patients) or 2 right and 1 left ventricular site (10 patients). Procainamide prolonged ERP. In drive, average ERP was 247 ± 5 ms (standard error of the mean) before and 277 ± 7 ms after procainamide ($p < 0.001$). The Q-T interval was prolonged by 50 ms in drive ($p < 0.001$), but Q-T prolongation did not reflect the increased ERP ($r = -0.05$). However, procainamide did not alter measured dispersion (54 ± 16 to 44 ± 14 ms in sinus, 48 ± 14 to 47 ± 13 ms in drive). Polymorphic ventricular tachycardia (VT) was induced in 6 patients in whom drive itself generally failed to reduce dispersion, and failure to induce tachycardia or shorter runs after procainamide was associated with narrowed dispersion. Polymorphic VT was not induced after procainamide in 2 patients with clinical episodes of torsades de pointes caused by type I agents. The mechanism of torsades de pointes was not explained by dispersion of refractoriness or by polymorphic VT initiated by premature beats after a type I drug.

Type I antiarrhythmic drugs cause Q-T prolongation and are sometimes associated with worsened or new ventricular tachyarrhythmias.[1,2] The latter might be explained by prolonged refractoriness signaled by the long Q-T interval or by nonuniform lengthening of refractoriness (dispersion), with asynchrony of repolarization marked by the long Q-T interval.[3] We examined Q-T intervals and dispersion of refractoriness as altered by procainamide (PA) and their relation to polymorphic ventricular tachycardia (VT), using extrastimulation at 3 disparate ventricular sites.

Methods

Twelve patients underwent ventricular extrastimulation in a nonsedated postabsorptive state for documented or suspected ventricular tachyarrhythmias after giving informed consent. All antiarrhythmic drugs were discontinued at least 5 half-lives before study and none of the patients was receiving beta-blocking agents. Digitalis and diuretics were withheld the morning of study. Clinical characteristics of the patients (Table I) were organized on the basis of torsades de pointes and subsequently induced polymorphic (VT). Two patients had torsades de pointes while receiving type I antiarrhythmic drugs, but the QT_c ($QT/\sqrt{RR}$) was ≤0.45 second in all patients at baseline. Six had coronary artery disease.

A quadripolar pacing catheter with an interelectrode distance of 1 cm was positioned at the right ventricular apex. Bipolar recordings were made from the proximal poles at filter settings of 30 to 500 Hz, using an Electronics for Medicine VR12 oscilloscopic recorder. Surface leads I, aVF, and V_1 were recorded as well. Additional bipolar pacing catheters were positioned at the right ventricular outflow tract and also within the left ventricle (10 patients) or at an additional right ventricular site (2 patients). Twice-threshold 2-ms extrastimuli were decrementally applied after each 8 sinus beats and 8 beats of ventricular drive at a cycle length of 500 ms using a Medtronics 5325 or a specially modified Bloom stimulator (Bloom, Reading, Pennsylvania)

One gram of intravenous PA was then infused at 100 mg/min or slower if hypotension developed. Extrastimulation was repeated within 10 minutes at the same 3 sites without catheter repositioning and blood was drawn for serum PA determination immediately thereafter.

The effective refractory period (ERP) was the longest coupling interval at which extrastimulation did not result in a propagated response. Dispersion of ERP was the range of effective refractory periods at the 3 sites. The Q-T interval, measured from the onset of the QRS to the point where the descending portion of the T wave met the isoelectric line, was

TABLE I Clinical Characteristics of Patients Studied

Case	Age (yr) & Sex	Structural Heart Disease	Clinical Ventricular Arrhythmias	QT_c
1	51M	CAD	NSVT	0.36
2	56M	CAD	None	0.42
3	60F	CAD	None	0.38
4	56M	CAD	NSVT	0.43
5	37F	MVP	Couplets	0.35
6	60M	None	Torsades	0.43
7	57F	CAD	Torsades	0.44
8	76M	CAD	NSVT	0.43
9	85F	None	NSVT	0.37
10	58F	None	NSVT	0.45
11	64M	CAD	NSVT	0.38
12	32F	None	NSVT	0.42

CAD = coronary artery disease; MVP = mitral valve prolapse; NSVT = nonsustained ventricular tachycardia, diagnosed as torsades (torsades de pointes) if sufficiently sustained to demonstrate sinusoidal rotation and return to original electrical axis; $QT_c = QT/\sqrt{RR}$.

corrected for sinus rate by the relation $QT_c = QT/\sqrt{RR}$.[4] Polymorphic VT was defined as multiform VT with a gradually changing electrical axis, sometimes resembling torsades de pointes. Data were compared before and after PA using a paired t test, and changes were related and compared with serum PA by linear regression.

Results

PA prolonged ERP (Table II). In sinus rhythm, the average ERP was lengthened by PA from 278 ± 8 ms (standard error of the mean) to 288 ± 8 ms (difference not significant [p = NS]) and the longest ERP from 307 ± 16 to 312 ± 12 ms (p = NS). The changes were small but cycle length was abbreviated, presumably in response to the decreased blood pressure after the infusion. With cycle length fixed at 500 ms by ventricular drive (Fig. 1), PA prolonged average ERP from 247 ± 5 to 277 ± 7 ms (p <0.001) and longest ERP from 276 ± 14 to 304 ± 13 ms (p <0.001). Dispersion of ERP was not widened by PA (from 54 ± 16 to 44 ± 14 ms in sinus rhythm, from 48 ± 14 to 47 ± 13 ms in drive; p = NS).

The average serum PA concentration was 5.4 ± 3 μg/ml (± standard deviation). Neither the change in average ERP nor that in dispersion correlated with serum PA (r = 0.11, −0.48).

Applying extrastimuli in 10-ms decrements, and anticipating a 15-ms increase in dispersion (the longest ERP had increased in drive an average of 28 ms), there is a 5% chance that we failed to detect an increase by evaluating only 12 patients. Alternatively, there is a 50% chance that we failed to detect a 6.5-ms increase in dispersion by studying only 12 patients.

Despite a faster heart rate and a reduction in dispersion, QT_c prolonged after PA, from 0.40 ± 0.01 to 0.48 ± 0.01 second (p <0.001). In drive, the Q-T interval lengthened from 0.38 ± 0.003 to 0.43 ± 0.01 second (p <0.001), but Q-T prolongation did not reflect the increased ERP (r = −0.05).

Polymorphic VT, sometimes resembling torsades de pointes, was induced in drive in 6 patients before PA was given. Of the 2 patients with spontaneous torsades de pointes while receiving type I antiarrhythmic drugs (Table I), only 1 had inducible polymorphic VT. After PA, polymorphic VT could not be induced in 3 of 6 patients (including the patient with spontaneous torsades de pointes presumably resulting from PA) and was briefer than that before the drug in the other 3. Patient 5 (Table II) had 37 beats of polymorphic VT induced using a drive cycle length of 600 ms, but only 3 beats after PA. The patient with clinical torsades de pointes presumably from quinidine did not have induced polymorphic VT either before or after PA. Polymorphic VT was induced in patients in whom drive itself generally failed to reduce dispersion (62 ± 25 ms sinus rhythm, 63 ± 27 ms with 500 ms cycle length drive). Prevention of induction or briefer polymorphic VT after PA was associated with decreased dispersion (in all, by 22 ms in sinus rhythm, by 8 ms in drive [Fig. 1]). In those without polymorphic VT, drive reduced dispersion by 24 ms, but PA did not (dispersion increased an average of 4 ms in sinus rhythm). None of these changes was

ERP,NSR = effective refractory period, normal sinus rhythm; ERP,500 = effective refractory period, ventricular drive at 500 ms cycle length; PVT = polymorphic ventricular tachycardia (maximum number of beats induced); SEM = standard error of the mean; VB = ventricular bigeminy; VT = ventricular tachycardia; (a) uniform sustained ventricular tachycardia. Patient 5 had prolonged PVT induced in the basal state at a drive cycle length of 600 ms (see text).

statistically significant, but possibly induction of polymorphic VT by postdrive extrastimuli reflected failure of drive to lessen dispersion, and less polymorphic VT after PA reflected narrowing of dispersion.

Discussion

Type I antiarrhythmic drugs may prevent ventricular tachyarrythmias partly by prolonging refractoriness. Differing effects on the diverging pathways of a potentially reentrant circuit can prevent reentry by making refractoriness uniform, converting unidirectional block to homogeneous propagation or to complete block. However, a drug prolonging refractoriness could have more effect on pathways already more refractory (increased sensitivity to the drug when there already is retarded repolarization). Further increased disparity of refractoriness would facilitate reentry, and we have found facilitated VT induction with widened tachycardia zones in response to extrastimulation in many patients with chronic recurrent VT.[5] This finding could explain arrhythmias associated with prolonged repolarization, such as torsades de pointes. Marked increased dispersion of refractoriness has been described in congenital Q-T prolongation syndromes.[6] Because type I antiarrhythmic agents can cause torsades de pointes when there is Q-T prolongation, we attempted to determine if these drugs can have a nonuniform effect on refractoriness to explain this arrhythmia.

PA prolongs ventricular refractoriness[7] and Levites et al[8] found PA to preferentially prolong refractory periods of the acutely injured canine ventricle, thereby reducing dispersion because ischemia shortened refractory periods. Michelson et al[9] studied 9 canine infarctions after 3 to 30 days, more closely resembling those of our patients with chronic ischemic disease. The dogs had inducible VT because of nonuniform injury caused by coronary reperfusion, but less inducible VT when PA prolonged refractoriness. However, in this chronic infarction model, PA did not consistently alter dispersion. Because we studied patients, we tested fewer sites, at longer basic cycle lengths, and selected patients without sustained arrhythmias.

Myerburg et al[10] found, in injured cat myocardium, that PA had its greatest effect when repolarization was shorter and its least effect when repolarization was longer. Action potential duration from healed (2 to 4 month old) myocardial infarction was longer than normal cells and prolonged after PA to a *lesser* extent than normal. Because tetrodotoxin affected both kinds of cells equally, this effect was not due to impaired delivery. ERP changes paralleled action potential changes, and the decreased differences after PA (decreased dispersion) correlated with loss of ability to induce sustained arrhythmias.

Induction of polymorphic VT analogous to torsades de pointes was not facilitated in our patients when PA prolonged their ERP and Q-T intervals, confirming the report of Horowitz et al.[11] Despite Q-T prolongation, PA actually tended to abbreviate dispersion measured in sinus rhythm when polymorphic VT became noninducible, more so than could be explained by a chronotropic effect from decreased blood pressure on its

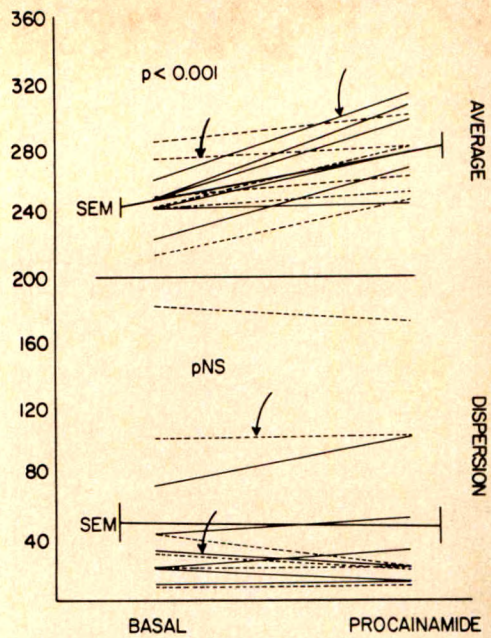

FIGURE 1. Average (**upper lines**) and dispersion (range, **lower lines**) of ventricular refractory periods before and after infusion of 1 g of procainamide. Mean and standard error of the mean are shown. Data refer to effective refractory periods measured with a ventricular drive cycle length of 500 ms. Average effective refractory period was prolonged ($p < 0.001$), but dispersion of refractoriness was not. The **dashed lines** indicate patients in whom polymorphic ventricular tachycardia was induced before procainamide, and the **arrows** refer to patients with clinical episodes of torsades de pointes.

infusion. That induction of polymorphic VT was not facilitated when PA prolonged the Q-T interval is difficult to relate to the mechanism of torsades de pointes because polymorphic VT is often not induced in patients with clinically recorded torsades de pointes.[12] However, when PA lengthened refractoriness and the Q-T interval, we did not detect widened dispersion of the ERP, even in patients with a history of torsades de pointes or previously induced polymorphic VT. This finding fails to substantiate the thesis that dispersion of refractoriness is a mechanism for torsades de pointes caused by type I agents, despite dispersion detected in patients with congenital torsades.[6]

We examined only 2 patients with torsades de pointes caused by drugs and perhaps measured an insufficient number of sites. Therefore, we may have failed to test those specific abnormal locations most sensitive to PA or with the longest ERP, that could respond to PA in an exaggerated fashion and result in marked dispersion. However, if the polymorphic VT we induced by extrastimulation was reentrant, the implication is that we did stimulate sites with sufficiently long ERP to permit unidirectional block. We found these sites with longer ERP not to be more sensitive to PA, consistent with Myerburg's observations[10] that sites with longer ERP are *less* sensitive to PA.

Thus, PA ameliorated induced polymorphic VT. Q-T prolongation by the drug did not signal further dispersion of the refractoriness we measured. These results might be unique to PA and cannot be extrapolated to

uinidine or disopyramide without separate trials. erhaps torsades de pointes is more commonly reported ith quinidine because quinidine *does* widen dispersion. lowever, we did not explain the mechanism of torsades e pointes by widening of dispersion or by polymorphic T in response to extrastimuli after a type I agent.

Exercise-Induced Bundle Branch Block

VICTOR S. WAYNE, MBBS (HONS), FRACP, RICHARD L. BISHOP, MD, LINDA COOK, LPN, and DAVID H. SPODICK, MD, DSc

Exercise-induced bundle branch block (BBB) is poorly understood. An investigation was made of its clinical, electrocardiographic, coronary angiographic, and myocardial scintigraphic characteristics, with follow-up data in 16 patients, aged 59 ± 9 (mean ± standard deviation) years, 11 who had left BBB and 5 who had right BBB. Fourteen had a preexisting baseline electrocardiographic abnormality; 11 had either incomplete BBB or nonspecific intraventricular conduction delay. Heart rates at onset of exercise BBB varied from 70 to 166 beats/min and in 9 patients the rates at BBB onset and offset appeared to be related, occurring within 8 beats/min of each other. Coronary artery disease (CAD) was diagnosed in 10 patients, cardiomyopathy in 2, and probable coronary spasm in 2. One patient had ventricular arrhythmias of uncertain origin, and 1 appeared to have no cardiac disease. Three patients had reversible thallium perfusion defects consistent with ischemia concurrent with developing BBB. The 3 patients in whom exercise BBB persisted all had CAD. Over a mean of 28 months of follow-up, only 1 patient had a morbid cardiac event—nonfatal myocardial infarction—and 2 died from noncardiac causes. Thus, exercise BBB primarily occurs in the context of cardiac disease, most commonly CAD, and concurrent ischemia may be demonstrable; the presence of "rate relation" does not militate against CAD.

There are well-recognized electrocardiographic (ECG) responses to myocardial ischemia, but little information other than case reports is available on the diagnostic and prognostic significance of exercise-induced bundle branch block (BBB). We assessed the clinical data, available coronary angiographic and scintigraphic information, and follow-up in 16 patients with this phenomenon.

Methods

Patient selection and exercise testing: Of 4,100 subjects who had exercise tests between February 1977 and February 1982, 16 (0.39%) had exercise-induced complete left or right BBB. Twelve were men and 4 were women, aged 45 to 76 years (mean 59 ± 9). Fourteen had maximal exercise with the standard and 2 with the modified Bruce protocol.

BBB criteria: *Left:* QRS ≥ 0.13 second; absent septal q; small or absent R waves with wide S waves in medial precordial leads.

Right: QRS ≥ 0.12 second; R′ in V_1 after 0.08 second; broad S in lead 1 and lateral precordial leads.

From the Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts, and the University of Massachusetts Medical School, Worcester, Massachusetts. Manuscript received February 22, 1983; revised manuscript received May 2, 1983, accepted May 4, 1983.

Address for reprints: David H. Spodick, MD, Director, Division of Cardiology, St. Vincent Hospital, 25 Winthrop Street, Worcester, Massachusetts 01604.

Coronary angiography and myocardial scintigraphy: Six patients had coronary angiography. Significant disease was defined as ≥50% luminal reduction in a major branch.

Eight patients had thallium-201 scintigraphy; perfusion was analyzed regionally as normal, reversible (consistent with ischemia), or irreversible (consistent with scarring).

Follow-up: Follow-up data were obtained from patients and physicians. Morbid cardiac events were defined as those that required hospitalization of the patient.

Results

Table I lists patient profiles, medications, test indications, baseline electrocardiograms, and exercise data.

Eleven patients had left BBB and 5 had right BBB during exercise.

Left BBB (11 patients): Nine patients had a prior ECG abnormality: 6 either incomplete left BBB or nonspecific intraventricular conduction delay (IVCD) (QRS ≥ 0.10 second), 1 nonspecific ST-T changes, 1 left ventricular hypertrophy, and 1 left-axis deviation and old inferior infarction.

Heart rates at left BBB onset varied from 70 to 166 beats/min and at offset from 66 to 131 beats/min. In 7 cases, offset rate was within 8 beats of onset rate. In 3 cases, onset and offset rates differed >25 beats. In 1 case, left BBB persisted beyond the recovery phase. Exercise was stopped in 1 patient because of onset of left

TABLE I Clinical Data

Case	Age (yr) & Sex	Medications	Indication for Test	Pretest ECG	Exercise BBB	HR at BBB Onset (beats/min)	HR at BBB Offset (beats/min)	Test End Point	Final Diagnosis

* The exact rates of onset and offset of exercise BBB in these 2 patients could not be determined, but are known to be within 8 beats/min of each other.

AP = angina pectoris; BBB = bundle branch block; CAD = coronary artery disease; Cor spasm = coronary artery spasm; D = dyspnea; ECG = electrocardiogram; F = fatigue; HR = heart rate; HT = prior hypertension; Inc. = incomplete; IVCD = intraventricular conduction delay; LAD = left-axis deviation; LVH = left-ventricular hypertrophy; M = methyldopa; MI = prior myocardial infarction; N = nitrates; P = propranolol; PLMI = posterolateral myocardial infarction; PMD = primary myocardial disease; PMI = posterior myocardial infarct; T = thiazide diuretic; VA = ventricular arrhythmias.

BBB. The onset rate of left BBB displayed no obvious relation to the maximum heart rate achieved with symptom-limited testing. In 4 patients, onset rate was ≤7 beats of maximum rate; 7 patients exercised to 25 to 60 beats/min higher than the onset rate of left BBB.

Right BBB (5 patients): All 5 patients had a prior electrocardiographic abnormality, 3 incomplete right BBB and 2 IVCD. Onset rates of right BBB varied from 7 to 130 beats/min. In 2 patients, BBB persisted past the recovery phase and in 3, right BBB offset occurred at 85 to 100 beats/min; in 2 of them, onset and offset rates were almost identical. One patient had right BBB several seconds before the end of the test; the other 4 reached 23 to 61 beats/min higher than at BBB onset.

There were no apparent differences between patients who had left versus right BBB with regard to age, sex, and clinical characteristics.

Coronary angiography: Angiography was performed in 6 patients, 4 with exercise left BBB and 2 with right BBB. Two patients had severe 3-vessel coronary artery disease (CAD) with diminished left ventricular function. One (Patient 14) had intermittent left BBB during contrast injection. One patient with exercise right BBB (Patient 7) had right coronary disease—50% proximal stenosis and 90% distal stenosis near the origin of the atrioventricular nodal artery. Patient 13 had normal coronary arteries but mild anterolateral left ventricular hypokinesia. He had left ventricular hypertrophy on the resting electrocardiogram and a normal echocardiogram and is regarded as having primary myocardial disease. Left BBB developed several times during catheterization, apparently related to positional changes and contrast injection; heart rates for left BBB onset and offset were not recorded. Two patients had

Myocardial scintigraphy: Six patients, 4 with left and 2 with right exercise BBB, had exercise thallium-201 myocardial scintigraphy. Three had reversible perfusion defects, 2 of which were associated with additional irreversible defects. Ischemic areas were posterolateral in 1 and anteroseptal in 2; 1 (Patient 5) had a normal study and 2 had irreversible perfusion defects only, 1 septal and 1 apical.

Follow-up: Patients were followed up for 7 to 69 months (mean 28). Two died, 1 at 7 months after exercise testing from carcinoma. He had a previous myocardial infarction. The other, who also had had a previous infarction, died from glioma 32 months after testing. Neither had any morbid cardiac events between exercise testing and death. Of the remaining 14 patients, Patients 4 and 14 had coronary bypass shortly after testing without postoperative morbid cardiac events. One patient (Patient 16) had an infarct during follow-up study. Three patients, all with documented CAD, have stable angina.

In summary, clinical and investigational data yielded diagnoses of CAD in 10 patients and myocardial disease in 2. Two had anginal pain and fluctuating ST-T changes but normal coronary angiograms, suggesting coronary spasm (heightened by an abnormal exercise thallium scan in 1). One patient (Patient 2) had ventricular arrhythmias without other evidence of cardiac disease. Only 1 was considered normal.

Discussion

There are very few data, and thus there is no consensus, regarding the significance of exercise-induced complete BBB. This is surprising, as BBB renders the ECG response to exercise inconclusive, producing a diagnostic and management dilemma.

Our study, to our knowledge the largest reported

What are the clinical and ECG characteristics of patients with exercise-induced BBB? Does it represent a hitherto uncharacterized response to ischemia? Is it more prevalent in patients with than without CAD, or is it a "rate-related" electrical phenomenon not necessarily occurring in the context of CAD? What is its prognostic significance?

Compared with the scarce data concerning exercise BBB, some information is available on intermittent BBB unrelated to exercise. Coronary angiography in patients with intermittent BBB demonstrates both normal and diseased coronary arteries. Lewis et al[1] reported on 12 patients with left BBB; of 4 with intermittent left BBB, 2 had significant CAD, 1 normal coronary arteries, and 1 patent ductus. In another report,[2] 5 had normal coronary arteries, 1 significant CAD, and another idiopathic cardiomyopathy. In another series,[3] among 5 patients with intermittent left BBB, 3 had normal coronary arteries and 2 had single-vessel CAD. Scintigraphy in this study, using rubidium-81 and potassium-43, produced a number of false-positive resting perfusion scans, which returned to normal with exercise in patients with angiographically normal coronary arteries versus those with CAD. Yet there were some equivocal exercise scintigraphic results. Of 8 patients with intermittent BBB, exercise scintigraphic results were only detailed in 4: 2 were normal, 1 had normal coronary arteries and no clinical problem other than intermittent BBB, and 1 had paroxysmal atrial fibrillation but did not undergo coronary angiography. Scintigraphy was equivocal in 1 patient who also did not have coronary angiography. A single patient with a positive result had 80% left anterior descending stenosis. Significantly, in view of our results, no mention was made as to whether those patients with intermittent BBB had an episode of BBB during their exercise tests, suggesting that they did not.

The scant reports specifically dealing with exercise BBB are less comprehensive. Goodfriend et al[4] described a man who had right BBB and left-axis deviation with exercise, but also with anxiety and amyl nitrite inhalation. He died suddenly. Autopsy revealed 3-vessel CAD, but no lesions >50%. There was intimal proliferation in the arteries of the atrioventricular node and His bundle and atrioventricular nodal fibrosis. On this basis, but without scintigraphy, the investigators suggested episodic ischemia as a cause for this otherwise apparently rate-related BBB.

A 30-year-old athlete with exercise BBB had also previously displayed intermittent left BBB that was felt to be rate-dependent, occurring at 78 beats/min with postural changes and minor activity and 85 beats/min at rest during right atrial pacing.[5] He had a normal angiogram and only developed exercise BBB at 180 beats/min. The results were interpreted as suggesting autonomic influences on intraventricular conduction rather than ischemia as the cause of BBB.

Four patients with severe CAD had transient left posterior hemiblock, rather than complete BBB, with exercise.[6] To ascertain if the hemiblock was due to new, transient ischemia or if it was rate-related, the investigators paced patients to induce tachycardia above the rate at which hemiblock appeared during exercise. When it could not be induced, they concluded that it was due to ischemia.

The only reported case of exercise BBB with simultaneous thallium perfusion imaging[7] demonstrated anteroseptal ischemia in a man with proved CAD who had left BBB during exercise, thus invoking active ischemia as a cause. The patient later had an anteroseptal infarct and permanent left BBB.

Such individual case reports and data make it difficult to ascertain patterns of cause, significance, or clinical features in exercise BBB. Sandberg[8] attempted to do so; he reported 9 patients, described from clinical data alone, without coronary angiography or scintigraphy. He divided the cohort into 2 groups. One, a generally younger group of 3 patients, had left BBB only at a high level of exercise and were felt to have no cardiac disease. The remaining 6 were generally older, developed left or right exercise BBB at rather light work loads, and were regarded as abnormal because of a cardiac history such as angina. However, of the 3 apparently normal subjects, 1 had a history of chest discomfort with stress and another had a ventricular septal defect. Moreover, of the 6 patients regarded as having heart disease on history alone, only 4 had angina pectoris and 2 had had rheumatic fever without subsequent heart disease. Thus, a classification of exercise BBB from these data is flawed.

Clinical and electrocardiographic characteristics: Our data do not suggest distinct age stratification in exercise BBB. A large proportion had a known, or highly likely, pretest diagnosis of CAD: 6 had had myocardial infarcts and 3 angina. The majority of patients had an ECG abnormality before exercise. Only 2 had normal baseline electrocardiograms; 11 had a baseline IVCD or incomplete BBB. The type of exercise BBB was related to the baseline electrocardiogram. Thus, the 3 patients with incomplete right BBB had complete right BBB and the patient with incomplete left BBB had complete left BBB. Of the 7 patients with nonspecific IVCD, 5 had left BBB.

The heart rates at onset and offset of exercise BBB are interesting, particularly in view of the common conception that "rate-related" BBB is often benign. Of the 13 patients in whom BBB remitted after exercise, in 9 the onset and offset rates were within 8 beats/min. Of these 9, 2 had reversible thallium perfusion defects, 4 CAD, 1 almost certainly coronary spasm, and 2 primary myocardial disease. In 4 patients, offset rates were at least 28 beats/min lower than onset rates. Two of these had CAD (1 with old infarct and another with angiographic 3-vessel CAD), 1 had ventricular arrhythmias without other evidence of heart disease, and 1 was normal. The 3 patients in whom exercise BBB persisted all had CAD, documented by angiography in 2 and prior myocardial infarction in 1. Thus, rate-related exercise BBB was associated with an appreciable incidence of CAD or myocardial abnormalities. Conversely, in the 4 patients with discordant onset and offset rates, in whom ischemia rather than rate would

Tachycardia-related BBB is regarded as "phase 3 block" [9] with prolonged recovery and increased duration of the action potential in part of the conducting system. This may be associated with hypopolarization, which slows conduction velocity. When electrical recovery is greatly prolonged, BBB may occur at relatively slow rates, explaining exercise BBB onset at rates in the 70s in 3 of our patients. Both prolonged recovery and hypopolarization of conducting tissue can be caused by ischemia and myocardial disease. Tachycardia itself may induce or aggravate ischemia by diminishing diastolic coronary perfusion time or by exceeding the ability of damaged His-Purkinje fibers to conduct, leading to exercise BBB.

In all 13 cases of reversible exercise BBB, offset rate of BBB was equal to the onset rate or lower. This is also consistent with phase 3 block, where differences in these critical rates have been explained by prolonged duration of recovery of the affected bundle and "linking," in which retrograde activation of the affected bundle from the normally activated ventricle perpetuates this pattern of ventricular activation even when heart rate is slowed to below the rate of BBB induction, over a variable rate range.[9]

Prognosis during follow-up study is also of interest, particularly in view of the Framingham study and other data[10–12] dealing with the significance of newly acquired BBB. New left BBB was associated with a high incidence of antecedent cardiovascular abnormalities,[10] particularly hypertension, cardiomegaly, and CAD. Subsequently, such patients had a high incidence of symptoms or complications of CAD and congestive heart failure and a mortality rate from cardiovascular disease and sudden death 5 to 10 times that of age-matched control subjects without left BBB[10,11] in a 5- to 10-year follow-up, but with significant differences already apparent before 5 years. New right BBB was also associated with antecedent cardiovascular abnormalities[12]; this included hypertension in as many as 60% of the cases. As with left BBB, new right BBB was later associated with a high incidence of symptomatic CAD, heart failure, and sudden death approximately 3 times that of control subjects.[12] New right BBB was not an independent contributing factor to the increased risk of developing cardiovascular disease, but rather, a marker of increased mortality in view of its association with disorders such as hypertension.[12] In men, new left BBB contributed independently to increased risk.[10]

Our patients also had a high prevalence of pretest cardiovascular abnormalities. Of the 11 patients with exercise left BBB, 5 (45%) had an antecedent prob 3 hypertension, 1 diabetes, and 1 ventricular arrh mias. Of the 5 patients with exercise right BBB, 3 hypertension and 1 had type IV hyperlipoproteine However, over a mean 28-month follow-up study, sequent cardiovascular problems have been few. Ne of the 2 patients who died (at 7 and 32 months exercise), both with prior infarcts, had further ca vascular complications before death from unrel causes. Of the remaining 14 patients, 2 had uncon cated coronary bypass and 1 (Patient 16) had a non anterior infarct at 27 months. No other patient h subsequent morbid cardiac event.

We conclude that exercise BBB is almost alway sociated with cardiovascular disease, mostly CA often displays a "rate-related" onset and offset develops when tachycardia causes or aggravates is mia or exceeds the capacity of a damaged conduc system. It is not invariably associated with high tality or morbidity.

James T. Willerson, MD

Now in its third issue, CARDIOLOGY is quickly becoming the annual of first choice for physicians and scientists in need of a well organized, easy-to-use review of the year's newest and most important developments in cardiovascular medicine and surgery.

It continues to be a multidisciplinary approach to clinical and applied research as useful to the expert as it is to the novice.

Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by,
Lawrence H. Cohn, MD,
Vincenzo Gallucci, MD

The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

Contributors from virtually every major cardiovascular center in the world that has had any meaningful experience with cardiac bioprosthetic valves participated in this symposium where 45 papers were presented in 8 categories.

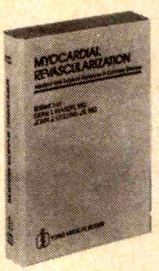
ISBN 0-914316-34-6, 596pp., illus., 1982, $65.00

Atlas Of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Foreword by David H. Spodick, MD

Dr. Alfredo Palacio has drawn on his rich experience to produce an atlas which presents in the simplest, most direct way possible the broadest range of normal and abnormal 2-dimensional echograms. Its excellent illustrations are complemented by beautiful drawings and supplemented by diagrams and explanatory texts which transcend the usual collection of illustrative material to explain methodology and provide the reader with a true "how-to-do-it" text. The descriptions and detailed illustrations in its technical sections should ensure the superior level of performance of echocardiographic techniques that is a *sine qua non* for good results.

ISBN 0-914316-35-4, 200pp., illus., large format 8¾ × 12, March '83, $65.00



Myocardial Revascularization

Medical and Surgical Advances in Coronary Disease

edited by
Dean T. Mason, MD,
John J. Collins, MD

The most up-to-date reference on the state-of-the-art of medical and surgical revascularization in clinical coronary disease available today. Presents many new therapeutic modalities not previously published anywhere.

"An excellent book on the major breakthroughs in an important area of medicine." MD magazine

ISBN 0-914316-31-1, 544pp., 1981, $60.00

Rehabilitation In Ischemic Heart Disease

edited by William P. Blocker, MD, David Cardus, MD

Heavily illustrated, this volume presents 60 self-contained chapters dealing with *all* aspects of rehabilitation of the patient with ischemic heart disease. The 52 noted contributors discuss topics such as: designing a cardiac rehabilitation center; methods of rehabilitation for the stroke patient, amputee, spinal cord injury patient who has had a heart attack; equipment needs for a cardiac rehabilitation center; legal responsibilities of the physicians and therapists, and much, much more.

BEHIND THE FACE OF HYPERTENSION

New evidence for central control

For the stress-provoked hypertensive

"Patients with essential hypertension may have exaggerated sympathetic nervous system responses to everyday stresses."[1]

Tablets of 0.1, 0.2, 0.3 mg

Catapres®

(clonidine HCl)

Hypertension

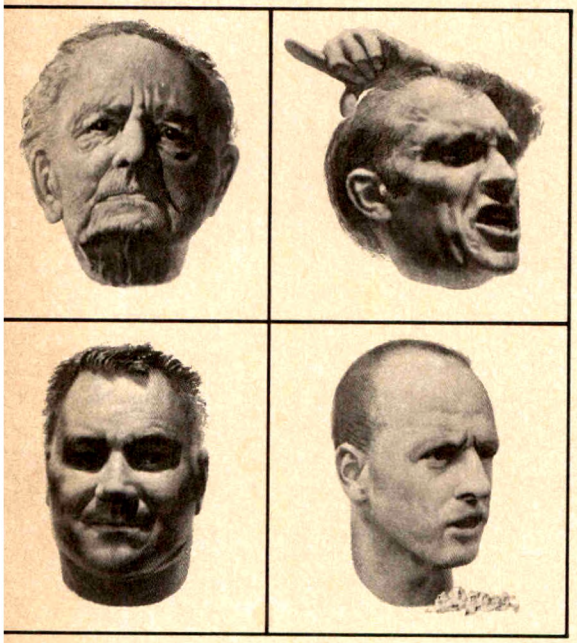
Central control

Please see last page for brief summary, including warnings, precautions, and adverse reactions.

EHIND THE FACE OF HYPERTENSION

ew evidence for central control

Catapres®
(clonidine HCl)
Hypertension



Catapres®

(clonidine hydrochloride)

Tablets of 0.1, 0.2, 0.3 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.
Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established.) These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres (clonidine hydrochloride) overdosage.

How Supplied: Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000 and unit dose package of 100. Also available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

For complete details, please see full prescribing information.

The one on the left has three times more adhesive surface.

Nitro-Dur™ (nitroglycerin) Transdermal Infusion System 10cm^2, on the left, has three times the adhesive surface area of the comparable Ciba product (5 mg). Nitro-Dur 20 cm^2 provides twice the adhesive surface area as the comparable Ciba product (10 mg). The wide adhesive strip assures good matrix-to-skin contact and helps keep the system sealed and in place. It also separates easily from the backing, for easy opening and application. By contrast, the Ciba product has minimal outside adhesion. The adhesive lies primarily on the central surface through which the drug must pass.

A wide adhesive strip. It's just one reason why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

The most widely prescribed transdermal nitroglycerin system.

Please see next page for a summary of prescribing information.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release in vivo of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[1] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

INDICATIONS AND USAGE: Prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28 and hospital packs of 100.

CAUTION: Federal law prohibits dispensing without a prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

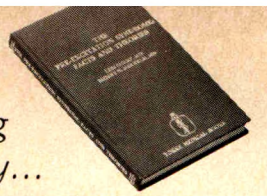
Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...



THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC
Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC
Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

Pacemaker-Mediated Tachycardias: A Rapid Bedside Technique for Induction and Observation

PHILIP O. LITTLEFORD, MD, R. CHARLES CURRY, Jr., MD, KERRY M. SCHWARTZ, MD, and CARL J. PEPINE, MD

The DDD pacemaker allows sensing and pacing in both chambers and can, therefore, maintain atrioventricular synchrony. However, this pacemaker creates an additional anterograde conduction system between the atrium and ventricle and, in the presence of ventriculoatrial (VA) conduction, the possibility of pacemaker-mediated tachycardia exists. A simple bedside technique that does not require catheterization or expensive equipment was used to detect VA conduction. Just after DDD pacer implantation, an attempt was made to detect VA conduction in 31 patients. Ambulatory monitoring (Holter) was done for 24 hours after implantation and at 2 to 4 and 6 to 8 weeks after implantation to detect pacemaker-mediated tachycardia. Attempts to induce pacemaker-mediated tachycardia were made using a special programmable externa stimulator at follow-up after implantation. It wa found that (1) all the 17 patients with detectable V conduction had pacemaker-mediated tachycardi when the atrial refractory period was less than th VA conduction time, (2) pacemaker-mediate tachycardias were not inducible or detected spor taneously when atrial refractory period was equa to or greater than VA conduction time + 50 ms, (3 VA conduction was not detectable in 9 of the 1 patients at a later visit. Six of these 9 receive antiarrhythmic therapy or had developed congestiv heart failure. VA conduction has important impl cations in patients with DDD pacemakers and ca be readily evaluated at the bedside.

Since the recent introduction of a pacemaker that senses and paces in both the atrium and ventricle (DDD or universal pacemaker), pacemaker-mediated tachycardias have been observed.[1–3] A pacemaker that senses spontaneous atrial activity and paces the ventricle accordingly is analogous to an "accessory" pathway. In the presence of intact retrograde ventriculoatrial (VA) conduction, this implanted "accessory" pathway provides the potential for a reentry type circuit. Recent observations by Furman[4] and others[5,6] suggest that pacemaker-mediated tachycardias are a very common problem with DDD pacemakers. It has been proposed that manipulation of atrial sensing or the atrial refractory period of this pacemaker may control or prevent these pacemaker-mediated tachycardias.[4,5]

These suggestions generate numerous questions: Does the presence of VA conduction uniformly lead to pacemaker-mediated tachycardias? Can pacemaker-m diated tachycardia be prevented by manipulation the atrial refractory period? Can the presence of V conduction be readily detected in patients with pac makers? Are there any clinical characteristics of V conduction which relate to the presence of pac maker-mediated tachycardias? The purpose of th study was to evaluate a simple bedside technique detect and measure VA conduction in patients wi DDD pacers. When VA conduction was detected, th relation between the duration of the VA conductic time and the pacemaker atrial refractory period w examined with regard to the presence or absence pacemaker-mediated tachycardia.

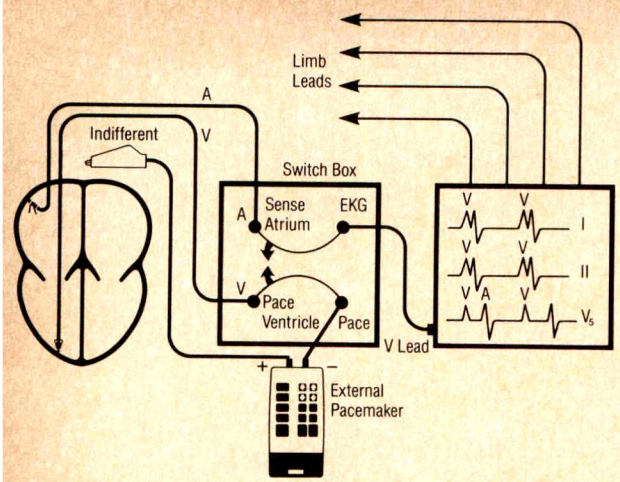
Methods

Patient selection: Patients with sick sinus syndrome, hea block, or both, referred for pacemaker implantation we considered candidates for this study. From January 4, 198 to September 14, 1982, 31 patients were selected. Sixteen we males and 15 females, average age 74 years. Each patient ga informed consent and a DDD pacemaker was implanted usi standard techniques.

Procedure: At the time of implantation, an attempt w made to detect VA conduction. This was accomplished aft

From the Florida Hospital, Department of Cardiology, Orlando, Florida, and the Department of Medicine, University of Florida and JHM Health Center, Gainesville, Florida. Manuscript received February 16, 1983; revised manuscript received May 2, 1983, accepted May 4, 1983.

Address for reprints: Philip O. Littleford, MD, 2400 Bedford Road, Orlando, Florida 32803.



IGURE 1. Connections and switching arrangements used to detect entriculoatrial conduction during implantation. A switching box (**center**) connected to the atrial (A) and ventricular (V) leads. The other side f the switching box is connected to the cathode of a standard external acemaker (**bottom**) and to the V lead of a standard 3-channel electrocardiographic recorder. The anode of the external pacemaker is onnected to an indifferent lead applied to the skin. This arrangement lows the ventricle to be paced with recording of the atrial electroam.

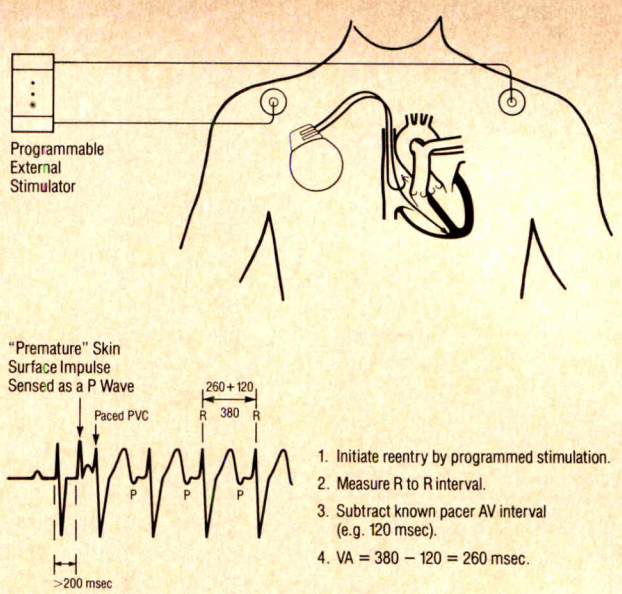


FIGURE 2. Induction of pacemaker-mediated tachycardia (PMT) by a programmed stimulator. A programmed stimulator is set to deliver an impulse to the skin 200 ms after the onset of ventricular depolarization. This impulse is sensed by the implanted DDD pacemaker atrial section as a P wave. After the programmed A-V interval, the DDD pacemaker stimulates the ventricle (paced PVC). When ventriculoatrial (VA) conduction is present, the atrium is depolarized (P), the pacemaker atrial section senses the P wave and again stimulates the ventricle, initiating PMT. VA conduction time is measured as outlined. PVC = premature ventricular contraction.

hreshold measurements, stabilization of the leads, and before he pulse generator was connected and the incision closed. When VA conduction was present, the duration was measured n milliseconds and termed *VA conduction time.* The VA onduction time was taken as the interval from the onset of he pacing artifact to the initial fast deflection of the atrial lectrogram. The implanted atrial and ventricular leads were ised for sensing and pacing, respectively, with a ventricular acing rate arbitrarily set at 90 beats/min. A special switching ox (Fig. 1) was used and allowed measurement of atrioventricular conduction as well. Depending on the type of pulse enerator used* the atrial refractory period (time of atrial onsensing after a sensed or paced ventricular event) was rogrammed to its shortest duration.

Twenty-four-hour electrocardiographic (ECG) recordings Holter) were made to determine the presence or absence of pacemaker-mediated tachycardia. After these recordings, VA conduction was detected, the pulse generator was reprogrammed so that the atrial refractory period was no less han 50 ms longer than the measured VA conduction time. his value was chosen in an attempt to select the shortest nterval that would compensate for variations in VA conuction. At the time of implantation, the actual programmed alues ranged from 50 to 100 ms. Another Holter ECG recording was then done in an attempt to detect a pacemakerediated tachycardia. The patient was then discharged. ostoperative visits were made between the second and fourth eek and again between the sixth and eighth week. At these sits, using a specially designed external programmable pulse enerator, attempts were made to initiate pacemaker-mediated tachycardia.

Technique used to attempt to initiate pacemaker-ediated tachycardia (Fig. 2): Two skin electrodes were tached, 1 to the right and the other to the left shoulder. An external pulse generator (Cordis Orthocor 1A overdriver, model 230A) was then attached to the electrodes and programmed to discharge an impulse at an interval ≥200 ms after the onset of ventricular depolarization detected from the electrocardiogram. This programmed impulse was delivered to the skin electrode and sensed by the atrial section of the pulse generator as an "atrial event." After the programmed atrioventricular interval, the pulse generator then paced the ventricle. When VA conduction was present, the atrium was activated in retrograde fashion. The atrial section of the pacemaker sensed the retrograde P wave and again paced the ventricle, initiating the pacemaker-mediated tachycardia. From ECG recordings made at fast paper speed, the paced R-R interval was measured. The pacemaker atrioventricular delay was subtracted to yield VA conduction time (Fig. 2). This was done with the pacemakers programed to upper rate limits (≥160 beats/min). The procedure was repeated 3 to 6 times and the VA conduction times recorded. The mean value was calculated.

Results

Of the 31 patients tested, in whom DDD pacemakers were implanted, VA conduction was detected in 17. Pertinent clinical and electrophysiologic data from these 17 patients are summarized in Table I. In 15, VA conduction was detected at implantation and in 2 when pacemaker-mediated tachycardia developed, within 2 hours of implantation (Patients RH and EM).

Of the 17 patients who had VA conduction detected in the hospital, VA conduction persisted in 12 at the first postoperative visit. In each case, the atrial refractory period of the pacer was ≥50 ms more than the VA con-

* Cordis Sequicor and Gemini units have programmable atrial refractory periods, whereas Medtronics Versatrax I and Telectronics ıtima have fixed atrial refractory periods of 155 and 200 ms, rectively.

* Absent at implant—present within 2 hours.
† "Dual pathways."
A fib = atrial fibrillation; AV = atrioventricular conduction time; CHF = congestive heart failure; Int = intermittent; SSS = sick sinus syndrom
VA = ventriculoatrial conduction time in milliseconds; VA_2 and VA_3 = VA measured at the first and second postoperative visits, respectively; VAo
= ventriculoatrial conduction time measured at operative implantation; 1° and 3° HB = first- and third-degree heart block.

duction time. In these 12 patients, VA conduction time at implantation was closely correlated with VA conduction time recorded at the first postoperative visit (Fig. 3). One patient died before the first visit (RC). In the other 4 patients, VA conduction was not detected at the first postoperative visit. One of these 4 patients (PB) was in congestive heart failure at the first visit; another (RB) had atrial fibrillation. One patient (LB) had very prolonged VA conduction measured at the time of implantation and in 1 (EM), no explanation wa found for the absence of VA conduction.

Of the 12 patients who had VA conduction detecte at the first postoperative visit, it was not detectable a the second postoperative visit in 7. Another (ES) ha the pacemaker removed because of infection. Thre patients (WE, HS, and RH) who now had congestiv heart failure had no VA conduction. Two patients (E'

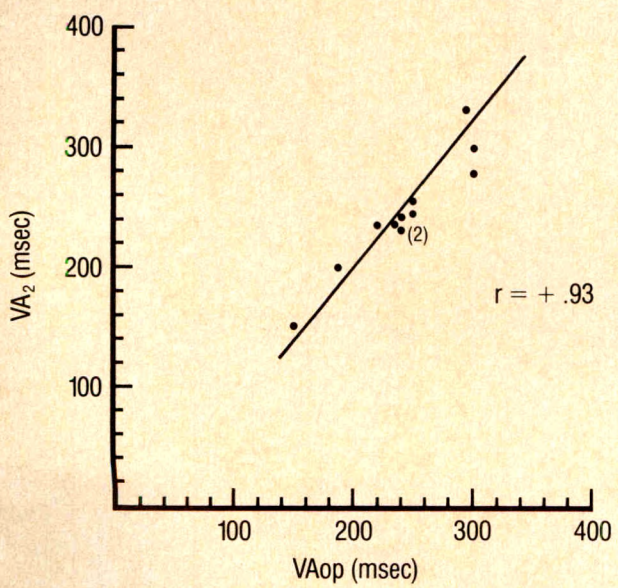

FIGURE 3. Relation of ventriculoatrial (VA) conduction time at implantation (VAop) to that at the first postoperative visit (VA_2) in the 12 patients who had detectable VA conduction at the first visit. When VA conduction persisted, its duration was relatively constant.

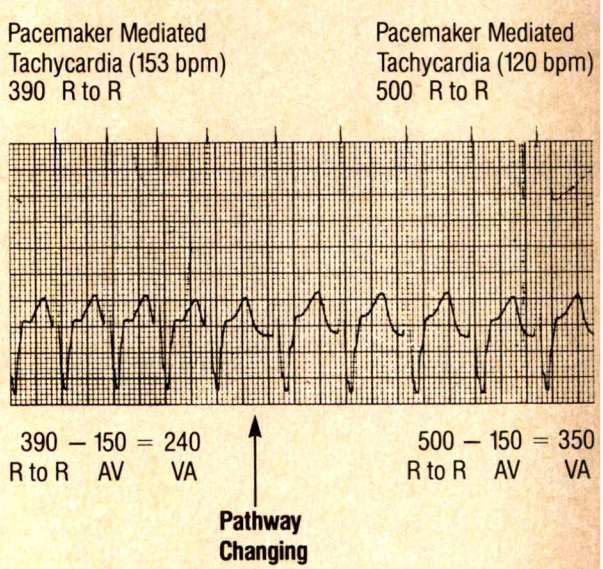

FIGURE 4. Changing pathways in pacemaker-mediated tachyca dias—example from 1 patient (JB) with pacemaker-mediated tach cardia occurring at 2 different rates. The A-V interval was fixed by th pacer and there was no evidence for atrial tachycardia, suggesting a ternate or dual pathways to explain the variation in ventriculoatrial (V conduction time. The upper rate limit in this patient was programme at 180 beats/min.

nd PD) were receiving antiarrhythmic therapy (pro-
ainamide and nadolol). In 1 patient (JO) there was no
pparent explanation for the absence of VA conduction.
nother patient (PB) died before the second visit.

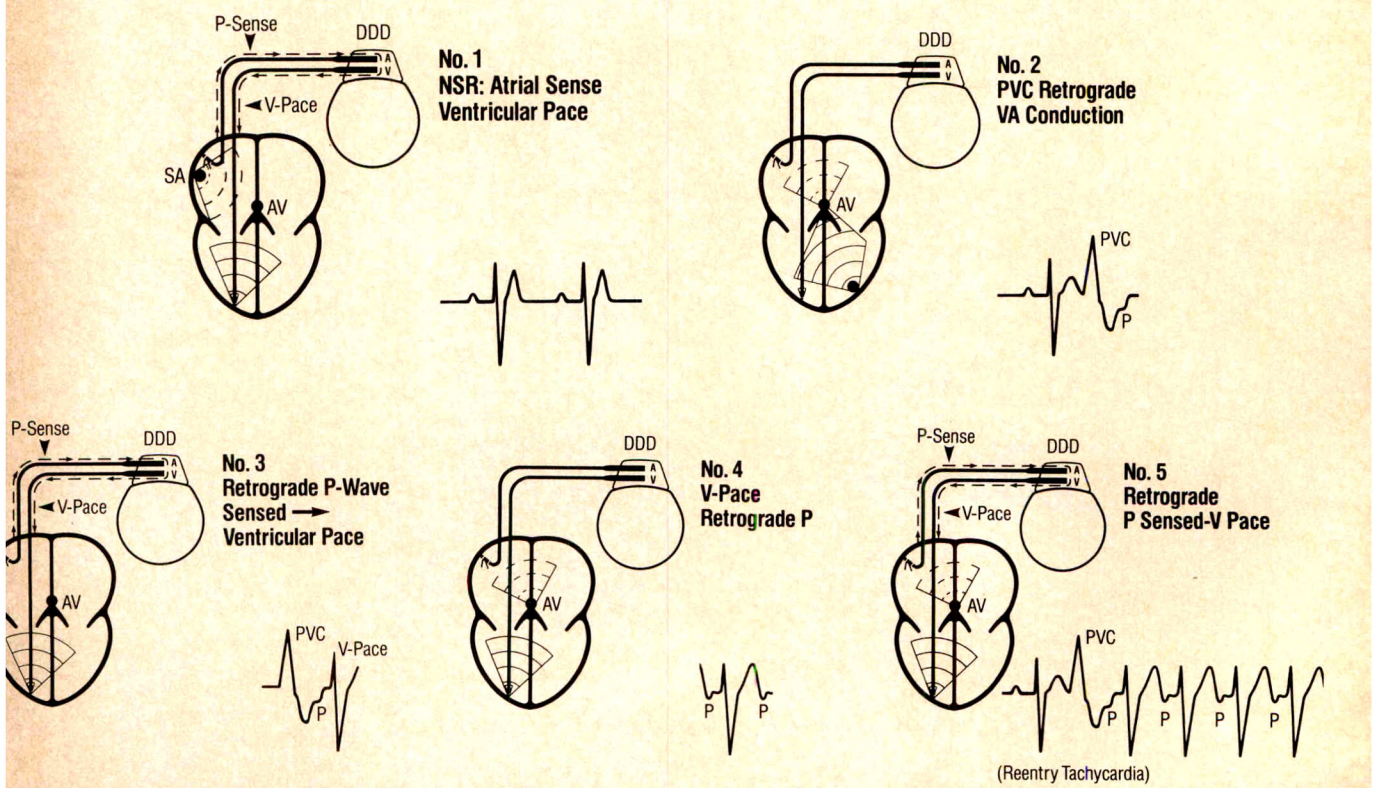
In the 17 cases with VA conduction, pacemaker-
ediated tachycardia occurred after a spontaneously
ccurring premature ventricular contraction in each
atient. In 15 of these 17 patients, the pacemaker-
ediated tachycardia rates were constant (±2%) for any
iven patient. Two patients (HK and JB) had pace-
aker-mediated tachycardia at 2 different rates. This
ggested the possibility of alternate or dual VA path-
ays, since the A-V interval would be fixed by the pacer
Table I, Fig. 4). Long multilead rhythm strips did not
ggest sinus tachycardia or atrial flutter. In both cases,
hen the pacemaker atrial refractory period was pro-
rammed to ≥50 ms more than the longest VA con-
uction time, pacemaker-mediated tachycardia could
ot be induced or seen by Holter ECG recordings.

Two patients (RH and EM) did not have VA con-
uction detected at implant; however, within 2 hours
f the procedure they had pacemaker-mediated
chycardia. At that time, relatively short VA conduc-
on times were found (150 and 185 ms, respectively).
t follow-up, when VA conduction was no longer de-
ctable, we could not initiate pacemaker-mediated
chycardia in either of these patients. One had devel-
ped congestive heart failure, but in the other there was
o apparent explanation for disappearance of VA con-
uction.

Discussion

Pacemaker-mediated tachycardias appear to be relatively common occurrences associated with DDD pacemaker implantation.[4–6] The most frequent initiating event appears to be a premature ventricular contraction. A DDD pacemaker can sense and pace in both the atrium and ventricle. Should the patient have a premature ventricular contraction and intact VA conduction, the potential to depolarize the atria in a retrograde fashion is present. If the pacemaker's atrial sensing is set so that the atrial refractory period is exceeded, the retrograde P wave will be sensed by the pacer and the ventricle will be paced after the appropriate delay. This sequence yields another retrograde P wave and the cycle continues (Fig. 5).

In 31 patients, we assessed VA conduction at implantation and twice after implantation using a simple bedside technique. Seventeen patients had detectable VA conduction and all subsequently had pacemaker-mediated tachycardia. Holter ECG recordings in these 17 patients revealed that a spontaneous premature beat triggered each tachycardia episode. In theory, any asynchronous beat could give rise to pacemaker-mediated tachycardia. For example, this could occur when the pacemaker is made asynchronous by brief application of a magnet or programmer. Another potential triggering event results when skeletal muscle signals are sensed by the atrial chamber, triggering the pacemaker to stimulate the ventricle.[3]



URE 5. Sequence that initiates pacemaker-mediated tachycardia by a premature ventricular contraction (PVC). AV = atrioventricular node; R = normal sinus rhythm; P-Sense = P wave sensed by atrial section of pacer; SA = sinoatrial node; VA = ventriculoatrial; V-Pace = ventricular ivation sensed by ventricular section of pacer.

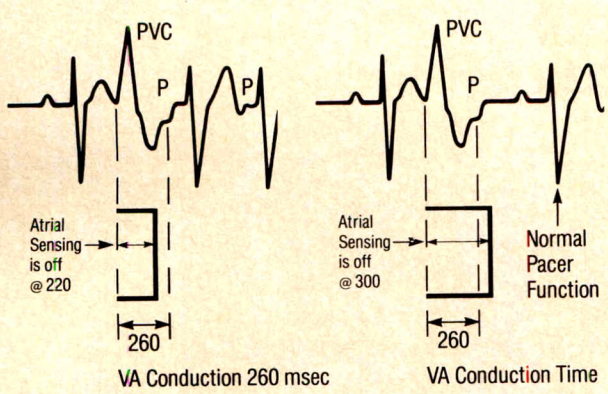


FIGURE 6. Importance of the relation of the atrial refractory period to ventriculoatrial (VA) conduction time in preventing pacemaker-mediated tachycardias. When VA conduction time is 260 ms (**left**) and atrial refractory period is 220 ms, the P wave resulting from conduction of the PVC to the atrium is sensed, resulting in pacemaker-mediated tachycardia. When the atrial refractory period is lengthened to 300 ms (**right**), the P wave is not sensed and normal pacemaker function results.

A potential problem with the method used to determine VA conduction time in outpatients is that it depends on the programmed upper rate limit of the pacemaker. Thus, if VA conduction time plus the programmed A-V interval time is less than the minimum allowable R-R interval because of upper rate limit constraints, the A-V interval will be artifactually prolonged by the pacemaker. In this case, subtracting the programmed A-V interval from the R-R interval gives an erroneous value for VA conduction time. This limitation was avoided by programming the pacemaker to high upper rate limits (≥160/ms).

The relationship of the pacemaker atrial (nonsensing) refractory period to the VA conduction time appears to be of central importance in controlling pacemaker-mediated tachycardia. This is illustrated in Figure 6. In this case, VA conduction time is 260 ms. When the atrial refractory period (atrial nonsensing) is 220 ms, the P wave can be sensed and the pacemaker-mediated tachycardia initiated. When the atrial refractory period is 300 ms, the retrograde P is not sensed and normal pacemaker function resumes after the premature beat. Since the pacemaker's atrial nonsensing or refractory period is constant, the constancy of VA conduction is most important. If the duration of VA conduction varied markedly with time, then control by reprogramming the atrial refractory period of the pacemaker would not be expected to influence the pacemaker-related arrhythmias in a predictable manner. In the group of patients we evaluated, VA conduction, when present, did not appear to vary significantly over time (Fig. 3). VA conduction time at the time of implantation was closely correlated with VA conduction time at the first postoperative visit ($r = 0.93$) in this subset of patients. Although VA conduction did not appear to vary significantly in this subset, procainamide, nadolol, and congestive heart failure were associated with absence of detectable VA conduction in some patients.

In 2 patients, we did not detect VA conduction at the time of the actual operative implantation procedure. Within several hours, they both developed pacemaker-mediated tachycardias with relatively short VA conduction times. Thus, the inability to detect VA conduction at the time of operative implantation may not necessarily mean that VA conduction will be absent at a later period.

In the first generation of DDD pacemakers, only 1 of the 3 frequently used pacemakers can vary the atrial refractory period. From our results, this programmable parameter is important for control of pacemaker-mediated tachycardia without addition of drugs to influence VA conduction or premature ventricular beats. From a practical point of view, it would appear relatively safe to set the atrial refractory period of the DDD pacemaker from 300 to 350 ms. This value includes settings that prevented tachycardia in all but 2 patients (WE and JB) in our series. If we assume A-V intervals of 125 to 150 ms, the shortest possible R-R interval would be (125 + 300) or 425 ms and the fastest heart rate would be 141 beats/min. At 150 ms, with an atrial refractory period of 350 ms, the shortest R-R interval would be 500 ms and the fastest heart rate 120 beats/min. This practice would limit the tachycardia rate to 120 or 140 beats/min.

In conclusion, VA conduction was detected frequently after DDD pacemaker insertion. Detection of VA conduction was uniformly associated with pacemaker-mediated tachycardia, and pacemaker-mediated tachycardia was prevented by manipulation of the atrial refractory period. When present over a period of time, VA conduction tends to be remarkably constant in duration, but may disappear in the setting of either congestive heart failure or antiarrhythmic therapy. An atrial refractory period of 300 to 350 ms should control pacemaker-mediated tachycardia in most cases.

Intermittent Preexcitation in the Wolff-Parkinson-White Syndrome

GEORGE J. KLEIN, MD and SAJAD S. GULAMHUSEIN, MD

Intermittent loss of the delta wave in the Wolff-Parkinson-White (WPW) syndrome may result from precarious conduction over the accessory pathway and, as such, would predict a benign prognosis in the event of the occurrence of atrial fibrillation (AF). We evaluated 52 consecutive patients referred for the assessment of the WPW syndrome and determined the prevalence of intermittent preexcitation using review of serial electrocardiograms, ambulatory monitoring, and treadmill testing. All patients subsequently had electrophysiologic testing using standard techniques to determine the properties of the accessory pathway. Of the 52 patients, 26 (50%) were found to have intermittent preexcitation as defined by loss of the delta wave with concomitant prolongation of the P-R interval on at least 1 occasion. These patients had longer effective refractory periods of the accessory pathway (356 ± 114 versus 295 ± 29 ms, mean ± standard deviation, $p < 0.05$) and longer shortest cycle lengths maintaining 1:1 anterograde conduction (426 ± 171 versus 291 ± 63 ms, $p < 0.02$) than their counterparts with constant preexcitation. During AF, 15% of patients with intermittent preexcitation had shortest R-R intervals between preexcited beats <250 ms, versus 50% of patients with constant preexcitation ($p < 0.01$). These data support the hypothesis that intermittent preexcitation suggests a benign prognosis in the event of AF. A careful search for intermittent preexcitation may yield important prognostic information in asymptomatic subjects and obviate further investigation.

The abnormal QRS complex in the Wolff-Parkinson-White (WPW) syndrome generally results from fusion between depolarization occurring via conduction over the normal atrioventricular conduction system and that occurring over an accessory atrioventricular (Kent) pathway with the delta wave resulting from preexcitation of the ventricle via the accessory pathway.[1,2] Intermittent preexcitation or intermittent loss of the delta wave has been observed[2–5] and generally attributed to a "low margin of safety" [6] of conduction over the accessory pathway, although other mechanisms have been proposed.[6–10]

Sudden death in the WPW syndrome can result from the occurrence of atrial fibrillation (AF) with a very rapid ventricular response due to conduction over an accessory pathway.[11] The purpose of our investigation was to estimate the prevalence of intermittent preexcitation in our referral population of patients with the WPW syndrome and to test the hypothesis that intermittent preexcitation correlates with a moderate ventricular response during AF.

Methods

The study group consisted of 52 consecutive patients referred to the Clinical Electrophysiology Laboratory at University Hospital between March 1980 and March 1982 for management of the WPW syndrome. Thirty-five patients had documented tachycardia (AF or reciprocating tachycardia), and the remaining 17 were asymptomatic, having been referred for evaluation as part of an ongoing natural history study of the WPW syndrome at our institution.

Intermittent preexcitation, defined as loss of the delta wave with concomitant prolongation of the P-R interval, was sought prospectively in all patients. Utilizing electrocardiograms (ECGs) forwarded by referring physicians and those recorded at University Hospital, at least 3 separate 12-lead ECGs were available for each patient. ECGs recorded during known antiarrhythmic medication were excluded. A 24-hour ambulatory ECG was obtained in all patients in the absence of antiarrhythmic medication. For this recording, the single lead displaying the most prominent delta wave was sought empirically. The tapes were scanned by a technician specifically instructed to focus on the presence or absence of the delta wave. All patients underwent a graded treadmill exercise test (Bruce) in the absence of medication. Standard 12-lead ECGs were recorded during each phase of this test.

TABLE I Clinical Profile

	Constant Preexcitation	Intermittent Preexciation
Age (mean ± SD [yr])	37 ± 13	40 ± 15
Male:female	19:7	13:13
Asymptomatic (%)	31	35
Multiple AP (%)	8	8
Septal versus free wall AP* (%)	46	54
Organic heart lesion (%)	11	11

* Only 4 patients had a right free wall accessory pathway, and 3 of these were in the intermittent group.

Data were compared using Student's *t* test; none were significant.

AP = accessory pathway; SD = standard deviation.

Patients were classified as having intermittent preexcitation if loss of the delta wave was observed on at least 1 occasion with the aforementioned investigations. All patients then underwent invasive electrophysiologic studies in the nonsedated, postabsorptive state in the absence of antiarrhythmic medication using methods previously described.[12,13] Informed consent was obtained before all studies. Specifically, incremental atrial pacing at 1 or more sites was performed to assess conduction over the accessory pathway, and atrial extrastimulus testing at 2 or more cycle lengths was done to determine the refractory period of the accessory pathway. The induction of AF was attempted in each patient if this arrhythmia did not occur spontaneously during the study.

Results

Determination of intermittent preexcitation: Twenty-six patients (50%) were found to have intermittent preexcitation. There was no difference in age, sex, symptomatic status, or location of accessory pathways in patients with and without this phenomenon (Table I). Eleven patients in the total study population were documented to have spontaneous AF, of whom 8 were in the constant preexcitation group.

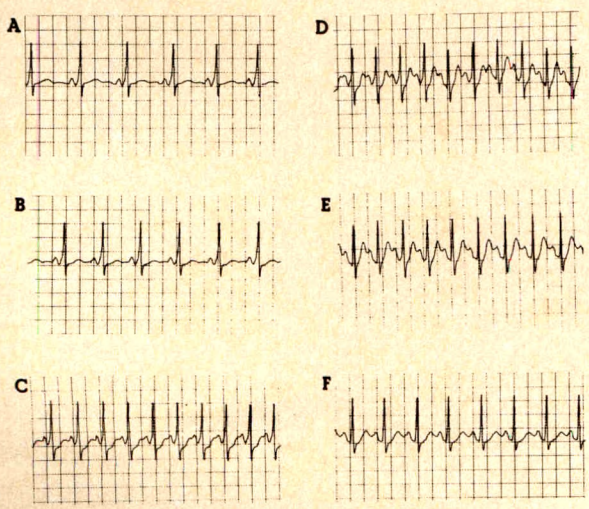

FIGURE 1. Loss of preexcitation occurring suddenly during the recovery phase of exercise testing. Lead II is shown. Preexcitation is present at rest (**A**) and during stress (**B and C**). Sporadic loss of the delta wave is seen in the early postexercise period (**D and E**). Normalization is constant in the later postexercise period (**F**), and this was observed in the other leads as well. The heart rate in **F** is slower than in **C**, yet the latter remains preexcited while the former is normalized.

Serial ECGs showed intermittent preexcitation in 14 patients. Nine patients had separate ECGs showing entirely normal or entirely preexcited QRS, while 2 patients showed sudden loss of preexcitation in the same tracing. Three patients exhibited both of the above patterns.

Seventeen patients lost preexcitation at the time of exercise testing. Normalization of the QRS occurred during exercise in 7 patients and during recovery in 1 patient (Fig. 1), and occurred sporadically in a single patient. Eight patients had a normal QRS at the onset of exercise, and 2 of the latter patients developed preexcited QRS during stress. Many patients appeared to lose preexcitation in 1 or more leads, while preexcitation was clearly persistent in other leads recorded simultaneously or nearly so (Fig. 2). The latter patients were not considered to have lost preexcitation. Only normalization of the QRS seen in all available leads and accompanied by P-R interval prolongation was considered to represent loss of preexcitation.

Twenty-one patients lost preexcitation during ambulatory monitoring (Fig. 3). Loss of preexcitation ap-

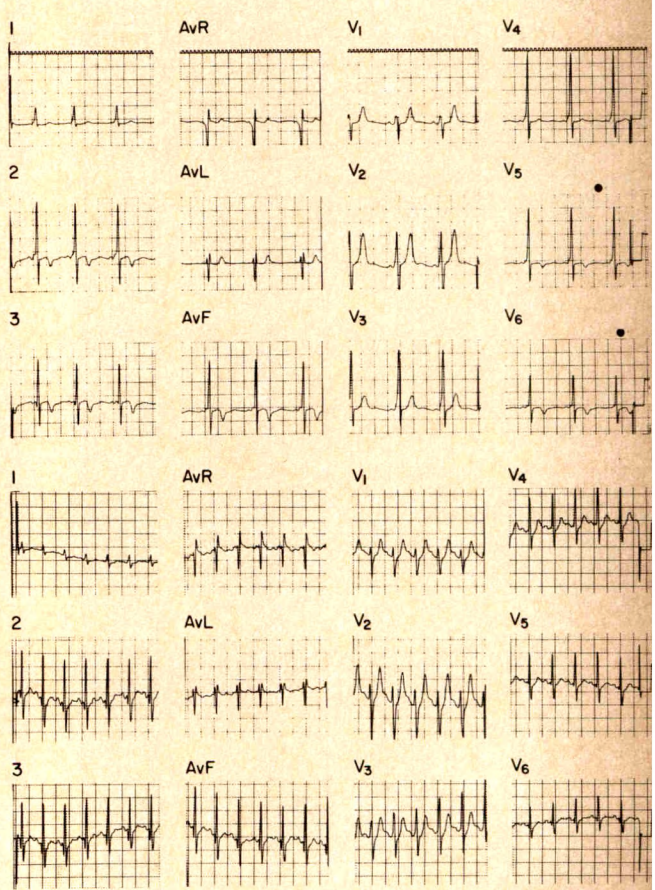

FIGURE 2. Apparent loss of the delta wave at peak stress. A delta wave is clearly present at rest (**top**). During maximum stress (**bottom**), the delta wave has disappeared from many leads, notably lead II (**2**). The normalization was accompanied by repolarization changes and an increase in amplitude of the P wave. A subtle delta wave is still present in lead V_3, indicating continued preexcitation and emphasizing the importance of examining multiple leads.

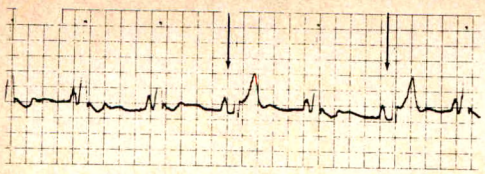

FIGURE 3. Sporadic, sudden loss of the delta wave (**arrows**) recorded during ambulatory monitoring. Loss of the delta wave is sudden and not accompanied by a change in heart rate. Repolarization changes accompany the loss of the delta wave.

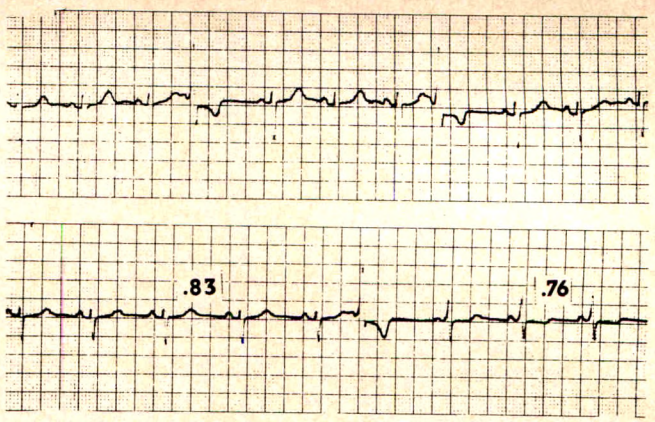

FIGURE 4. Sudden appearance of preexcitation after premature atrial contraction (PAC) (**lower panel**) recorded during ambulatory monitoring. The heart rate is slightly faster after the appearance of the delta wave, but no consistent relationship was observed in this record. Numbers represent R-R intervals in seconds.

peared related to a critical heart rate in 2 patients and was sporadic in 12 patients (Fig. 4). Seven patients had only a normal QRS during ambulatory monitoring.

Electrophysiologic testing: As a group, patients with intermittent preexcitation demonstrated a longer anterograde effective refractory period of the accessory pathway at comparable cycle lengths and a longer minimum cycle length, maintaining 1:1 conduction over the accessory pathway (Fig. 5). Thirteen of 26 patients with constant preexcitation had very rapid rates due to anomalous conduction during AF (shortest R-R interval between preexcited beats, 250 ms), versus 4 of 26 with intermittent preexcitation ($p < 0.01$, Fig. 6). The use of 250 ms as a cut-off was based on a previous study of ventricular fibrillation in the WPW syndrome[11] in which all WPW patients with this complication had shortest R-R intervals <250 ms during AF induced in the laboratory.

Resting P-A, A-H, and H-V intervals were similar in the 2 groups. Six patients with intermittent preexcitation had no retrograde conduction over the accessory pathway, versus 5 patients with constant preexcitation. The minimum cycle length maintaining 1:1 retrograde conduction over the accessory pathway was 305 ± 105 ms (mean ± standard deviation) for patients with intermittent preexcitation, versus 300 ± 60 ms for patients with constant preexcitation.

Discussion

Intermittent loss of the delta wave has been consistently observed by investigators of the WPW syndrome, but the mechanism underlying this phenomenon is not known.[2,9,14–17] Our data demonstrate that patients with

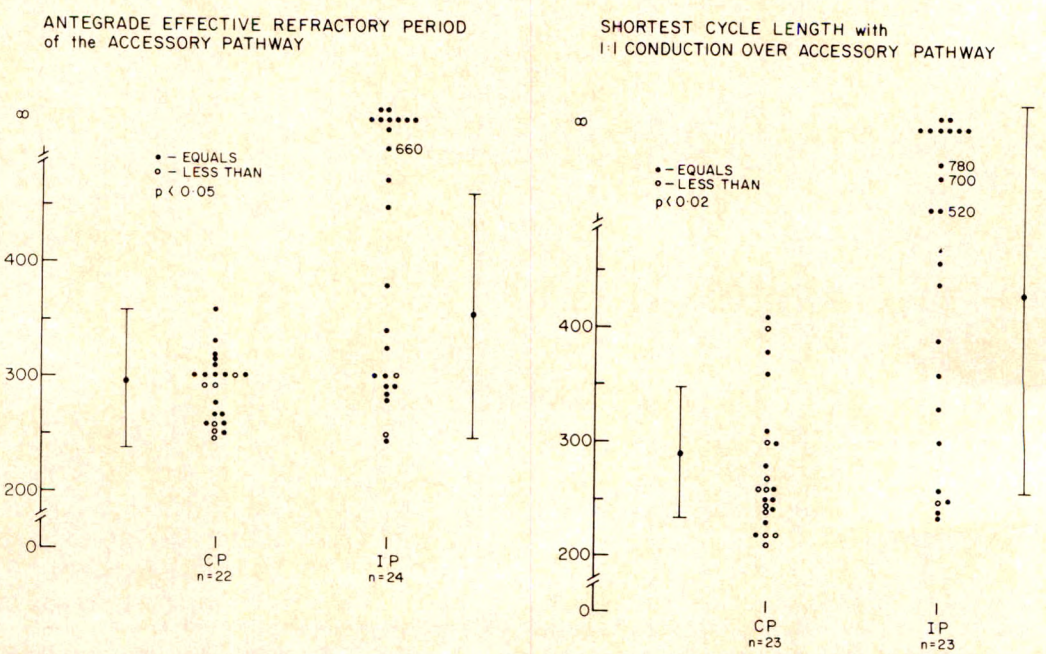

FIGURE 5. Anterograde effective refractory period (cycle length 600 or 700 ms) of the accessory pathway (**left panel**) and shortest cycle length with 1:1 conduction over the accessory pathway (**right panel**). Comparison between patients with and without intermittent preexcitation is shown. CP = constant preexcitation; IP = intermittent preexcitation; ∞ = no preexcitation at any paced cycle length. (The means do not include values designated as ∞, and consequently the actual significance is probably underestimated.)

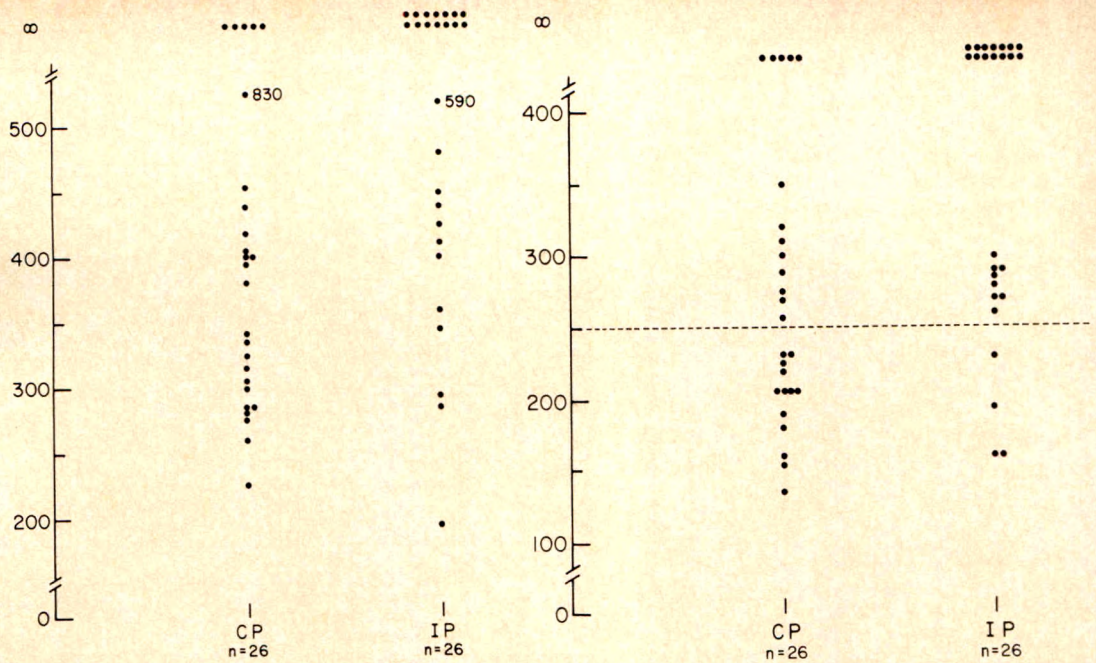

FIGURE 6. The average R-R interval (**left panel**) and shortest R-R interval between preexcited beats (**right panel**) during atrial fibrillation. Comparison of patients with and without intermittent preexcitation is shown. Fifteen percent of patients with intermittent preexcitation (IP) had a shortest R-R interval between preexcited beats <250 ms versus that in 50% of patients with constant preexcitation (CP) ($p < 0.01$). ∞ = no preexcited complexes during atrial fibrillation. (The means are not calculated because most patients with intermittent preexcitation had values designated as ∞.)

intermittent preexcitation have a longer refractory period of the accessory pathway and poorer conduction over the pathway than patients with constant preexcitation. In fact, 14 of 26 patients with intermittent preexcitation had no preexcited QRS during AF (Fig. 6). This supports the hypothesis that intermittent preexcitation is a manifestation of an accessory pathway with "precarious" conduction. This finding may have significant clinical relevance in the management of asymptomatic or minimally symptomatic patients with the WPW syndrome. Sudden death may occur in these patients and is usually related to AF occurring in the setting of an accessory pathway with a short anterograde refractory period.[11] The finding of intermittent preexcitation would suggest that the heart rate during AF would be moderate and would not degenerate into ventricular fibrillation. Conversely, the finding of constant preexcitation was not helpful.

The prevalence of intermittent preexcitation as determined largely by serial follow-up of ECGs or ambulatory monitoring has ranged from 25 to 76%,[2,9,14–18] whereas normalization of the QRS with exercise occurs less frequently, in 3 to 29% of patients.[9] Strasberg et al[19] observed sudden QRS normalization and concomitant P-R prolongation during exercise in 4 of 36 WPW patients and further observed that these patients had accessory pathways with relatively long anterograde refractory periods. This group also emphasized the frequent occurrence of QRS normalization without P-R prolongation and pointed out that the latter was related to "enhanced atrioventricular nodal conduction" rather than true loss of preexcitation. In our series, intermittent preexcitation was observed in 27% of patients by review of serial ECGs, in 46% by use of serial ECGs and ambulatory monitoring, and in 50% using serial ECGs, ambulatory monitoring, and treadmill testing. Loss of preexcitation was generally sporadic and not related to a critical heart rate, an observation also made by others.[2,18,20] It is possible that more prolonged observation periods would have increased the observed prevalence of intermittent loss of the delta wave.

Four patients with intermittent preexcitation were observed to have rapid ventricular rates during AF (shortest R-R interval between preexcited beats <250 ms) and appear to contradict the general findings. Although the mechanism for loss of the delta wave in these patients must remain speculative, the key issue is whether apparent normalization of the QRS represented total loss of preexcitation. Ohnell[2] defined "pseudonormalization" as apparent loss of the delta wave with subtle preexcitation still present. Pseudonormalization occurred gradually, whereas true normalization was abrupt and was usually accompanied by repolarization changes. In 3 of our patients in this group loss of a subtle delta wave occurred during ambulatory monitoring of a single lead. It is possible that a single lead may show apparent normalization when this is not verified by inspection of other leads[15] (Fig. 2). One of the foregoing patients had 2 accessory pathways (septal left lateral), and it is possible that the interplay of multiple accessory pathways could cancel the delta wave in some leads.[6] The fourth patient in this group had loss of a small delta wave with P-R prolongation at maximal exercise. The difficulties of interpretation of preexcitation during stress testing have been emphasized.[5] Changes in body position as well as atrial and ventric

ular repolarization could result in apparent loss of the delta wave, especially when the latter is subtle. Finally, one cannot rule out the possibility of a striking dependence of accessory pathway conduction on sympathetic tone in some patients,[21,22] resulting in presence or absence of anomalous conduction. We feel that the latter 4 patients may not have truly lost preexcitation, but that interpretive difficulties were created by a subtle delta wave viewed only in a single lead or during maximal exercise. In support of this, no patient exhibiting sudden (Mobitz 2) normalization of a prominent delta wave was found to have rapid AF due to anomalous conduction.

Malignant Hypertension in Women Aged 15 to 44 Years and Its Relation to Cigarette Smoking and Oral Contraceptives

DIANA B. PETITTI, MD, MPH, and ARTHUR L. KLATSKY, MD

To study the factors associated with malignant hypertension in young women, we reviewed the medical records of all women aged 15 to 44 years who were hospitalized in any of 15 affiliated hospitals from 1971 to 1980 with malignant hypertension. There were 15 new patients in this period, an incidence of 0.5 per 100,000 women of these ages per year. Four women had underlying renal disease. All of the remaining 11 used oral contraceptive smoked cigarettes, or both. Nine were white, ar 6 women had normal blood pressure in the 2 months before hospitalization. These findings su port a relation of oral contraceptive use and cig rette smoking to an increased risk of malignant h pertension in young women.

We studied the factors associated with malignant hypertension in women aged 15 to 44 years. We did so because a number of case reports of malignant hypertension in oral contraceptive users have appeared,[1–11] but the frequency of the condition in young women is unknown.

Methods

We used computer-stored hospital discharge records from a multihospital database for the years 1971 through 1980 to identify women aged 15 to 44 years who were hospitalized with a diagnosis of malignant hypertension (ICDA-8 Codes 430.0-430.9). After reviewing their medical records, we retained in this series only nonpregnant women with a first diagnosis of malignant hypertension, as characterized by very high blood pressure (BP) (diastolic >160 mm Hg or systolic >220 mm Hg) and papilledema with retinal hemorrhages or exudates or renal or cardiac failure. The medical records were used to determine race, oral contraceptive use, cigarette smoking, a history of systemic hypertension, and most recent pre-illness BP.

The denominator used to calculate the incidence rate of malignant hypertension was the number of woman-years of observation in the population served by the hospitals among women 15 to 44 years old for 1971 to 1980.

Results

Fifteen women aged 15 to 44 years had a first diagnosis of malignant hypertension in the years 1971 to 1980. The incidence of the disease in this age group was 0.5 cases per 100,000 women per year. Four of t women had an underlying disease: 1 chronic glomer lonephritis, 1 lupus erythematosis, 1 scleroderma, a 1 right renal artery stenosis due to fibromuscular dy plasia. Two of these women smoked cigarettes and o used oral contraceptives.

Table I describes the 11 women who had maligna hypertension and no underlying disease. All of the either used oral contraceptives, smoked cigarettes, both. Nine were white. Five had normal BP measu ments documented in the medical record in the months before admission and another had been told a physician that her BP was "normal" 4 months bef admission.

Discussion

Malignant hypertension is very rare in women childbearing age in this population. In this series, as others,[12] many of the patients with malignant hyp tension had an underlying disease. Of particular inter here are the characteristics of the patients witho underlying disease: all of them used oral contraceptiv smoked cigarettes, or both. Many had normal BP bef the onset of the disease; only one was black. Pr studies[12] have emphasized malignant hypertension a complication of renal or hypertensive disease, though its infrequent occurrence in the absence of eit had been recognized.[13,14] Our data suggest that in you women, a large subset of cases of the disease occurs women who were entirely healthy until its occ rence.

A fairly large number of oral contraceptive users w malignant hypertension have been reported in t medical literature,[1–11] although an epidemiologic stu

† History of hypertension associated with oral contraceptive use only.

of the condition has not been done. Based on data from surveys of use of birth control methods among adult women in the United States in the 1970s,[15] we estimate that 2 oral contraceptive users would be expected among 11 women the ages of our patients. Thus, this study provides evidence that the risk of malignant hypertension is increased in oral contraceptive users.

The relation of malignant hypertension to cigarette smoking has been reported.[16,17] Our data provide support for a relation to smoking: 7 of 11 patients with the disease were smokers, although only 4 would be expected based on natural estimates of the percentages of cigarette smokers in women.[18]

The pathogenesis of malignant hypertension is not known with certainty. Linton,[19] Isles,[16] Kincaid-Smith,[20] Gavras,[21] and their co-workers suggested similar explanations: Vessel injury sets off intravascular coagulation, either accompanied or caused by microangiopathic hemolytic anemia, and the intravascular coagulation then perpetuates the vessel injury, setting up a vicious cycle. The importance of a relationship between oral contraceptive use and malignant hypertension in the context of this mechanism lies in observations that oral contraceptive use is associated with hypercoagulability, manifested in an increase in the risk of thromboembolic disease,[22,23] and with intimal vascular lesions.[24]

Both oral contraceptives[25] and smoking[26] are associated with lower concentrations of a stable metabolite of prostacyclin (PGI_2), one role of which is to limit the extent of thrombus formation at sites of endothelial injury. Untreated hypertensive patients have a higher concentration of a stable metabolite of PGI_2, which reverts to normal when blood pressure is lowered pharmacologically.[27] Roy et al[27] suggest that enhanced vessel wall PGI_2 synthesis may protect against organ damage in patients with hypertension. Perhaps smokers, oral contraceptive users, and small subgroups of hypertensive patients who have impaired vessel wall PGI_2 synthesis or enhanced degradation have malignant hypertension because of the absence of this protective mechanism. We cannot confirm this hypothesis, but we believe further research on malignant hypertension might explore an alteration in PGI_2 regulation, production, or degradation as a mechanism underlying the

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Prescribing Information

Tablets of 50 mg
Tablets of 100 mg

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions Impaired Hepatic or Renal Function: The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications**, **Warnings**, and **Precautions**.

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings**.

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

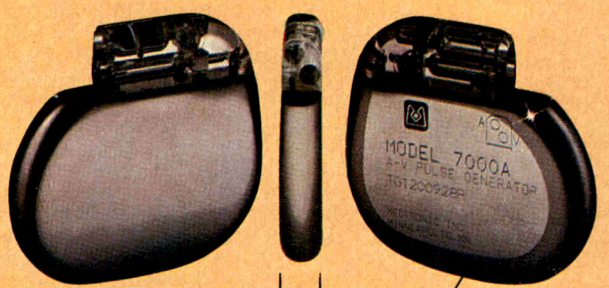
New VERSATRAX II

	340 ms.		235 ms.
THE FEATURE:	Atrial Refractory 340 ms. after a PVC...	A-V Sequential Pacing following a PVC...	Automatic Atrial Refractory adjusts to 235 ms. during A-V synchrony...
PATIENT BENEFIT:	To block sensing of retrograde when your patient needs it most	To restore synchrony	To track rapid atrial rates

Keeps a heart beating like a heart.

The most physiologic pacemaker.



52 grams 10mm Anti-muscle-stimulation coating

New Versatrax II Model 7000A is:

- **Automatic Atrial Refractory**
  The advanced physiological method of tracking the atrium and discriminating retrograde
- **Smallest**
  The most physiological size and shape available
- **Superior Sensing Performance**
  Medtronic's exclusive patented circuitry rejects most myopotentials
- **Plus ... uniquely from Medtronic**
  - A-V Pacing System Analyzer—Model 5311
  - Endocardial screw-in leads—Models 6957/6957J
  - Follow-up choices—Cardiocare™/Teletrace™
  - Educational programs
  - Service options
  - Proven reliability

Versatrax™ II Model 7000A Universal A-V Pacemaker

Intended Use

The Model 7000A universal A-V pulse generator has a wide range of application in patients requiring permanent cardiac pacing where restoration of A-V synchrony and/or sinus modulated rate variability is indicated to improve cardiac output or to protect against arrhythmias related to the sequence of cardiac impulse propagation.

With the Model 7000A programmed in the A-V universal (DDD) mode, indications may include:

- Some of the sick sinus syndrome conditions such as intermittent sinus bradycardia, sinus arrest or SA block.
- Intermittent or complete atrioventricular block with normal sinus activity.
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V interval settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

In the A-V sequential (DVI) mode, the Model 7000A may have application in the following:

- Sick Sinus Syndrome (sinus bradycardia, sinus arrest, SA block, and the brady-tachy syndrome).
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V delay settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

At any time, the Model 7000A can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry (e.g., atrial lead malfunction).

NOTE: The Medtronic® Model 7000A universal A-V pulse generator is under clinical investigation in the U.S. The procedures for using this pulse generator, as well as its safety and efficacy, will be evaluated during this investigational study according to the Clinical Investigation Protocol. Therefore, the "Intended Uses" section is based on Medtronic's experience with other physiologic pulse generators. No claims for safety and efficacy can be made for the Model 7000A pulse generator during its clinical investigation. Patients should be advised that the Model 7000A pulse generator is under clinical investigation.

Contraindications

General: There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician.

DDD Mode: The DDD mode is contraindicated in the presence of atrial fibrillation, atrial flutter and rapid atrial rhythms or slow retrograde conduction.

DVI Mode: In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation or flutter.

Warnings

Diathermy: Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site.

Electrosurgical Units: Electrosurgical units should never be used in the vicinity of unipolar pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead.

Defibrillation: Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. Positioning a magnet or the programming head over the pulse generator makes it subject to programming. A nominal vertical magnetic field strength of 90 Gauss (in a field measured 1½ inches from the magnet's surface) from a magnet at 1¼ inches from the reed switch is required to initiate asynchronous pacing. Do not use electrocautery, diathermy, or any other source of electromagnetic interference in the vicinity of the patient once a magnet or programming head has been positioned over the pulse generator. If an electrocautery unit is used, the physician may prefer to program the pacemaker to asynchronous pacing prior to the procedure.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

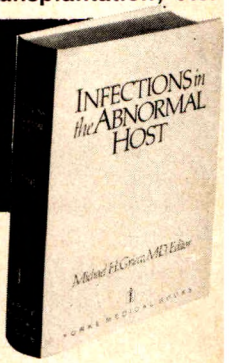
INFECTIONS
IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color



Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy • Index

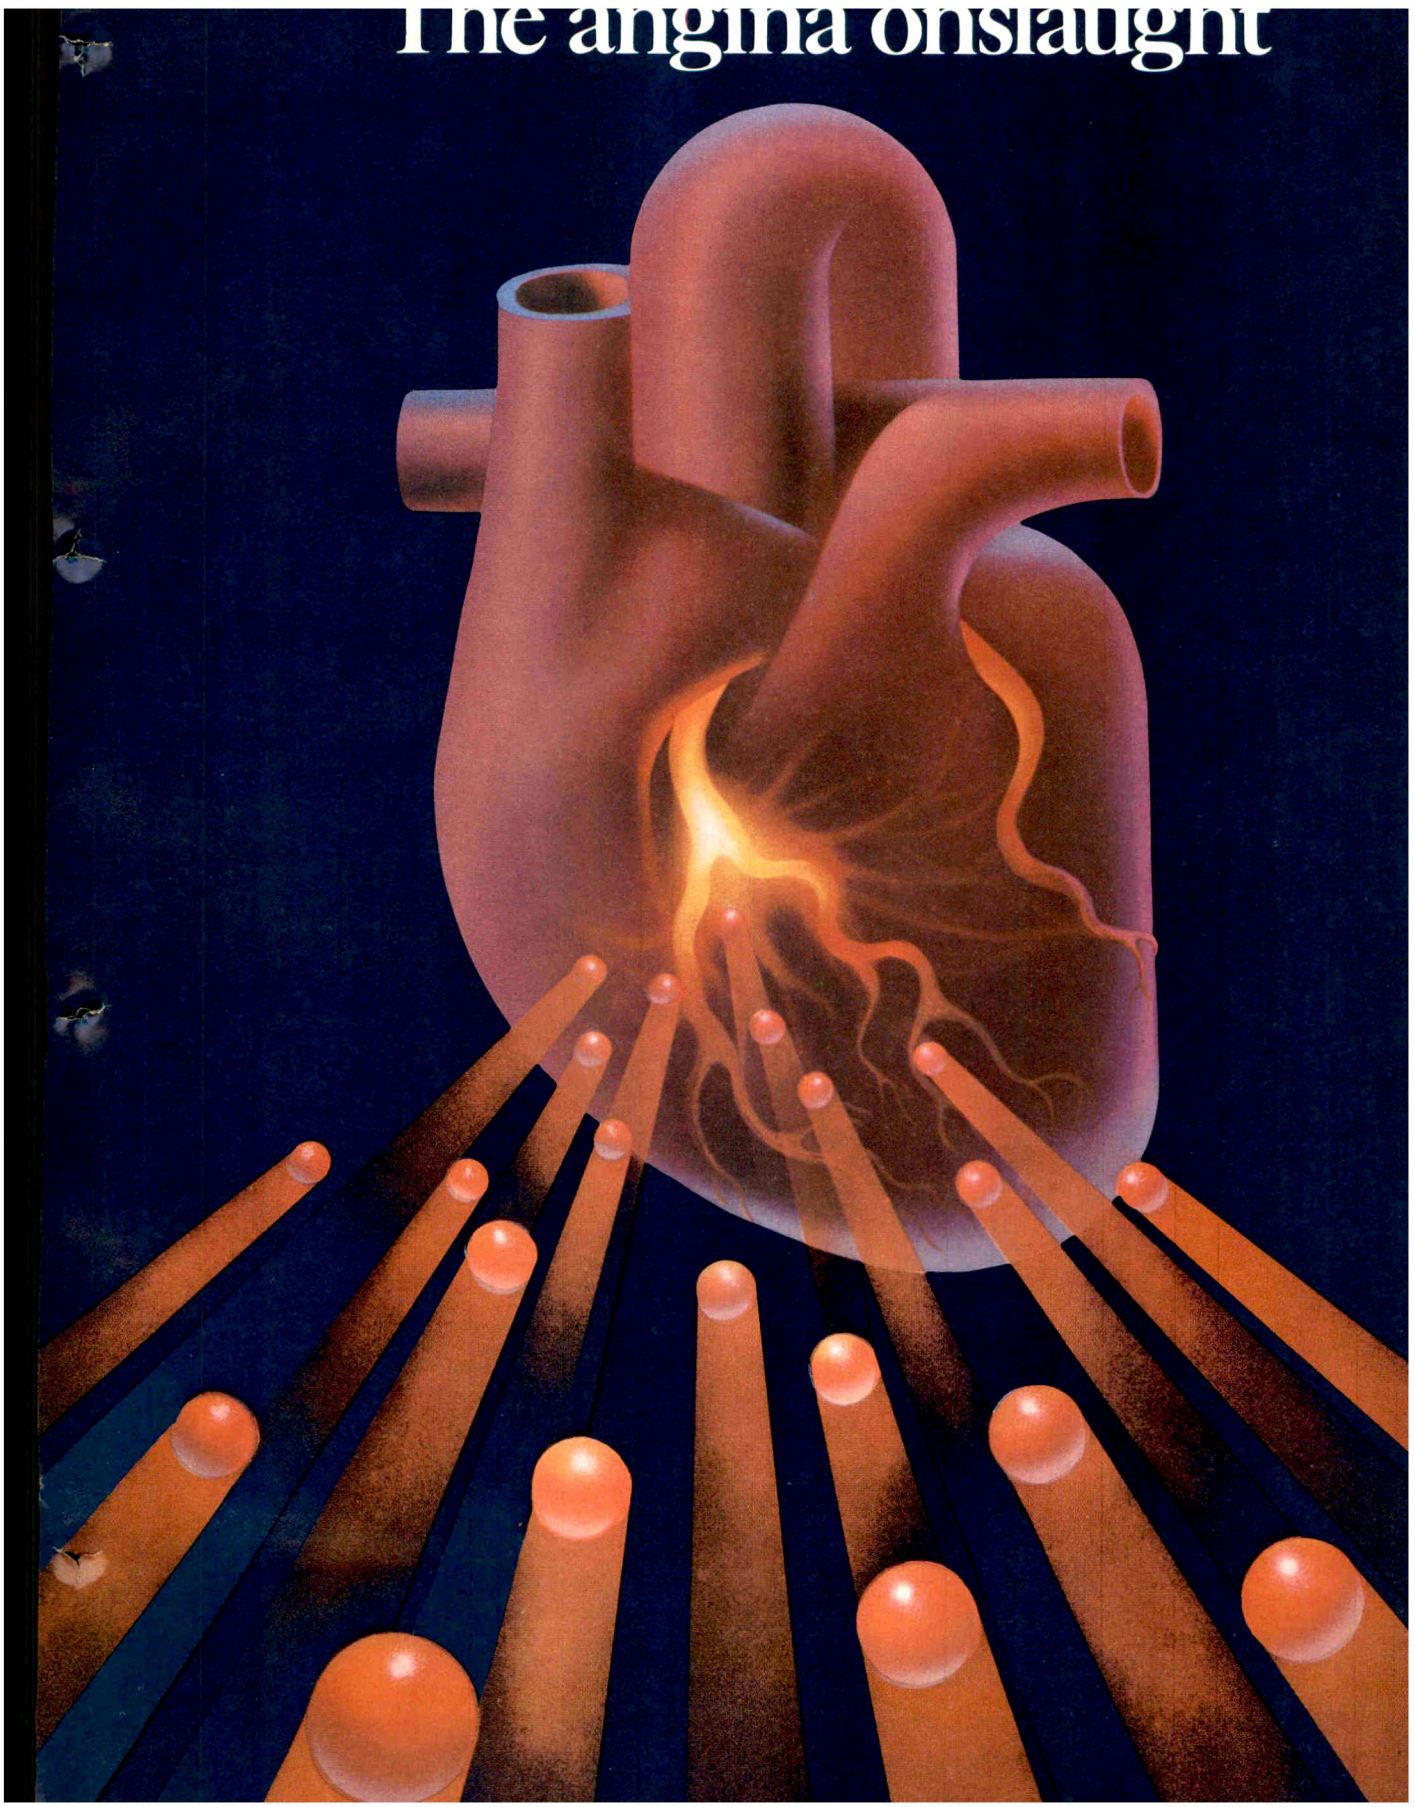
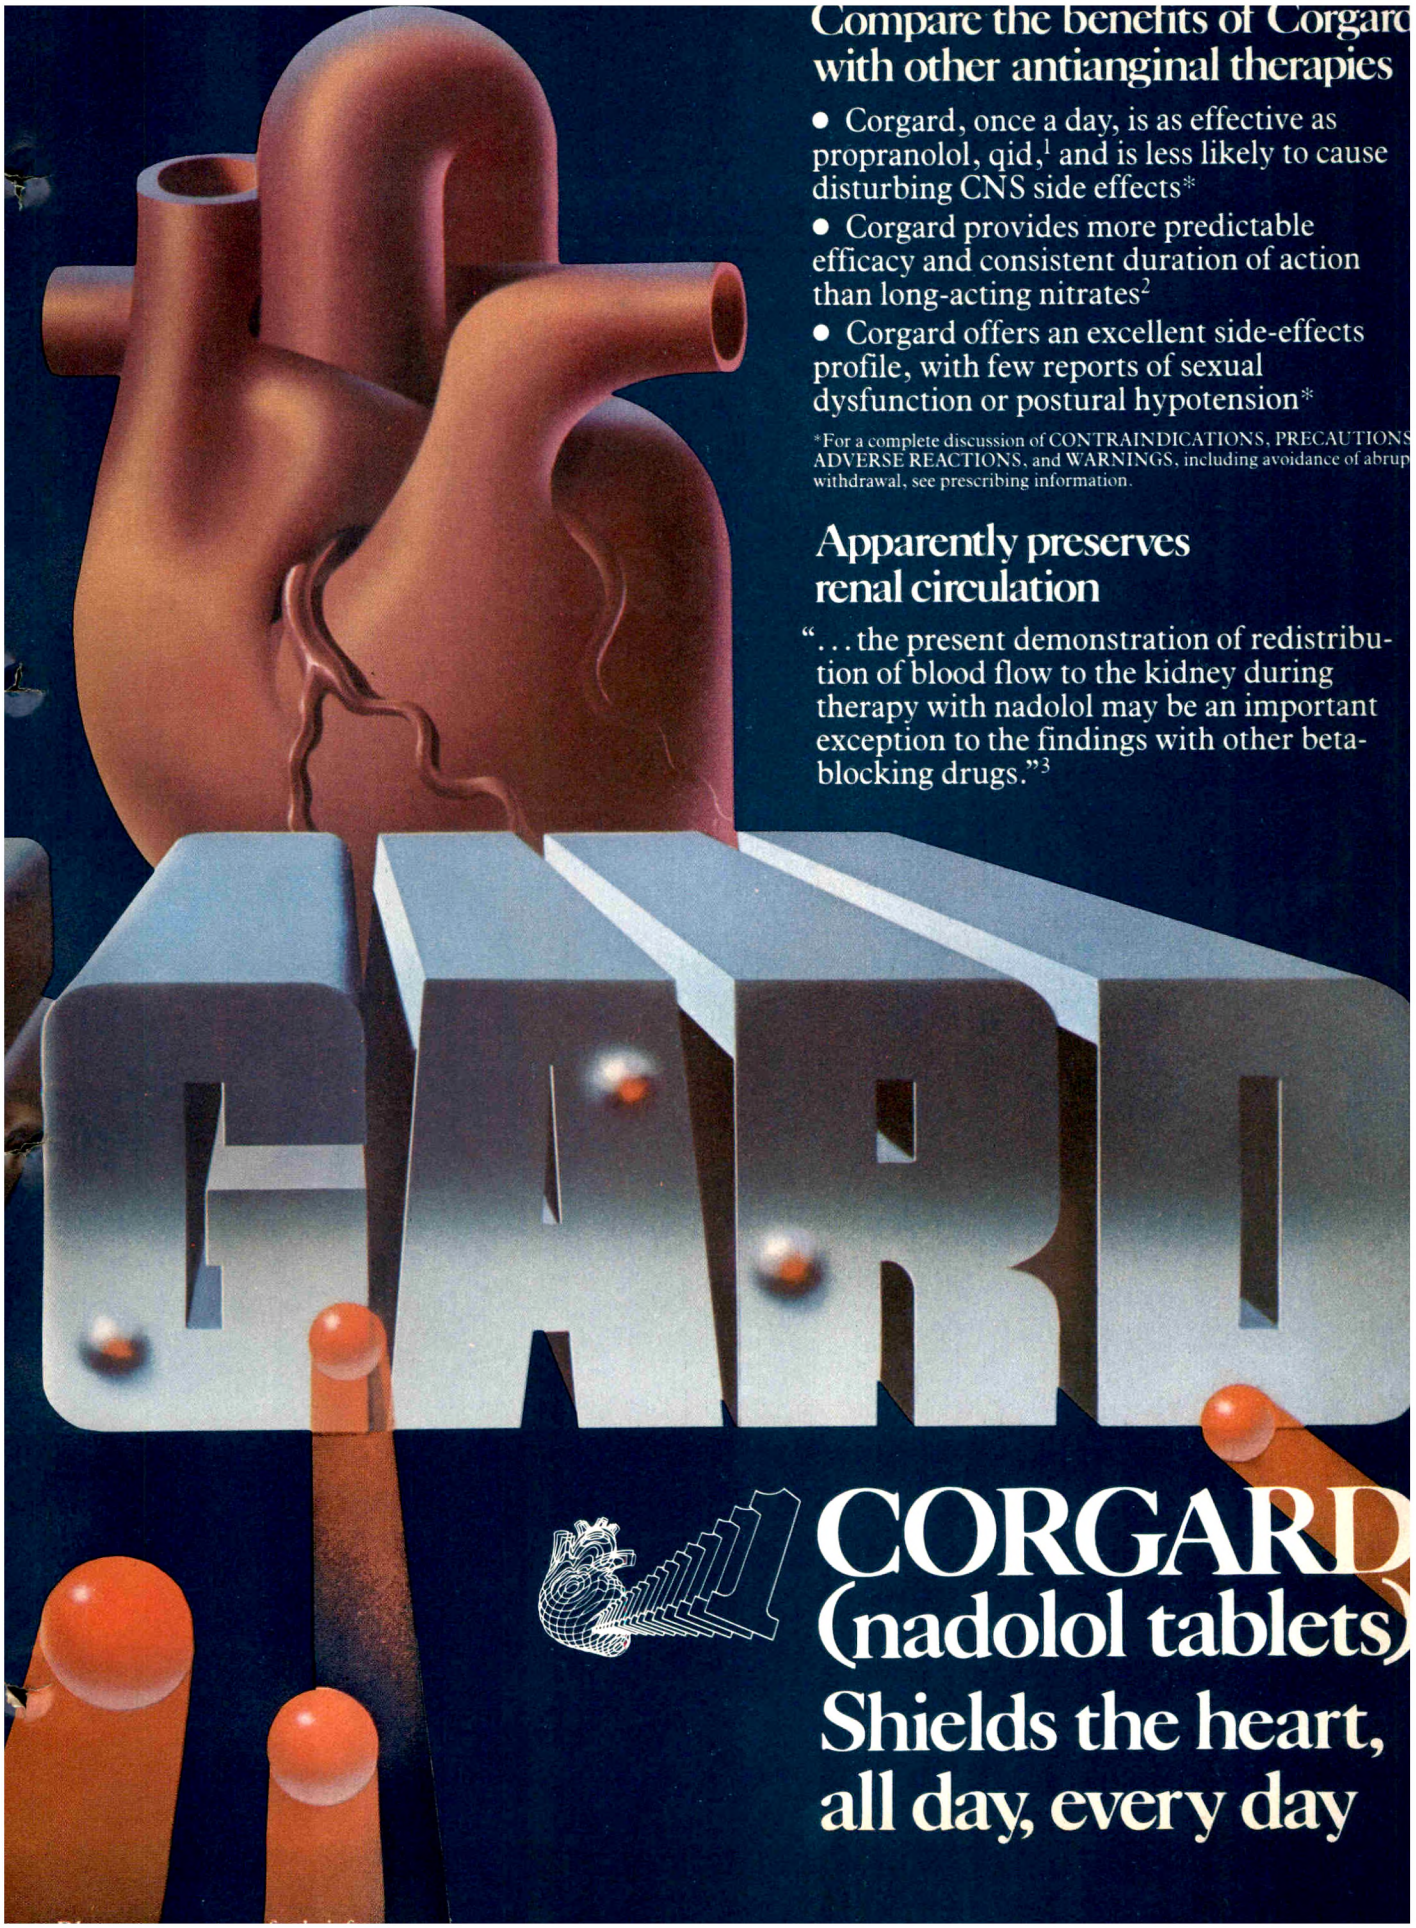
The angina onslaught



The angina shield:
CORGARD®
(nadolol tablets)

SQUIBB®



Compare the benefits of Corgard with other antianginal therapies
• Corgard, once a day, is as effective as propranolol, qid,[1] and is less likely to cause disturbing CNS side effects*
• Corgard provides more predictable efficacy and consistent duration of action than long-acting nitrates[2]
• Corgard offers an excellent side-effects profile, with few reports of sexual dysfunction or postural hypotension*
*For a complete discussion of CONTRAINDICATIONS, PRECAUTIONS, ADVERSE REACTIONS, and WARNINGS, including avoidance of abrupt withdrawal, see prescribing information.
Apparently preserves renal circulation
"...the present demonstration of redistribution of blood flow to the kidney during therapy with nadolol may be an important exception to the findings with other beta-blocking drugs."[3]
GARD
CORGARD
(nadolol tablets)
Shields the heart, all day, every day

CORGARD®
(nadolol tablets)
Once a day for angina pectoris

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure — Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery — Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

Nursing Mothers — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

Pediatric Use — Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System** — Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory** — Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal** — Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous** — Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

Potential Adverse Effects: Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System** — reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal** — mesenteric arterial thrombosis; ischemic colitis. **Hematologic** — agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic** — fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous** — reversible alopecia; Peyronie's disease; erythematous rash.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm — Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most patients respond to 160 mg or less daily). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets. The 40 mg and 80 mg tablets are also available in convenience packages containing 4 blister cards of 7 tablets each.

Determinants of Circulatory Response to Intravenous Hydralazine in Congestive Heart Failure

JOHN R. WILSON, MD, MARTIN ST. JOHN SUTTON, MD,
J. SANFORD SCHWARTZ, MD, NANCY FERRARO, RN, and NATHANIEL REICHEK, MD

To determine whether the circulatory response to hydralazine in heart failure is influenced by initial hemodynamic status or left ventricular (LV) chamber size, 28 patients with chronic LV dysfunction were studied. Hemodynamic measurements and echocardiographic LV end-diastolic dimension were correlated with the response to 20 mg of intravenous hydralazine and to a dose titrated in each patient to reduce systemic resistance by ≥20%. Hydralazine, 20 mg, decreased systemic resistance from 23 ± 8 to 18 ± 8 U ($p < 0.01$) and increased the cardiac index from 2.0 ± 0.5 to 2.5 ± 0.6 liters/min/m² ($p < 0.01$) and the stroke work index from 21 ± 11 to 24 ± 9 g·m/m² ($p < 0.05$). Titrating the dose to decrease systemic resistance by ≥20% increased the cardiac index further to 2.7 ± 0.6 liters/min/m² and the stroke work index to 32 ± 9 g·m/m². The change in systemic resistance produced by 20 mg of hydralazine correlated only with initial systemic resistance ($r = 0.53$), suggesting that vascular response to hydralazine is a direct function of initial vascular resistance. The percentage change in stroke work index produced by 20 mg of hydralazine correlated directly with indexes of LV preload–end-diastolic wall stress ($r = 0.69$) and pulmonary wedge pressure ($r = 0.43$) and inversely with stroke work index ($r = -0.49$), an index of ventricular work. Similar but less close correlations were observed when the dose of hydralazine was titrated. The hemodynamic response to hydralazine did not correlate with LV end-diastolic dimension or right atrial pressure. Thus, vascular response to moderate doses of hydralazine is related to initial systemic vascular resistance. LV pump response is related to the level of initial LV pump dysfunction but not to LV chamber size or right atrial pressure.

Hydralazine is a direct smooth muscle vasodilator widely used in the treatment of patients with congestive heart failure (CHF). This agent usually augments cardiac output and stroke work in such patients.[1–4] However, in a substantial subgroup of patients, hydralazine produces little or no hemodynamic improvement.[2,3] Accordingly, there has been growing interest in identifying physiologic or pharmacologic factors that determine a patient's response to hydralazine, so that patients most likely to benefit from hydralazine can be identified.[4]

The present study investigates whether the vascular and left ventricular (LV) pump response to moderate doses of hydralazine in patients with heart failure is related to their initial circulatory status or to LV chamber size. Intravenous hydralazine was used to avoid potential problems with variable gastrointestinal absorption of the agent. Vascular responsiveness was assessed by examining the effect of 20 mg of intravenous hydralazine on systemic vascular resistance. The LV pump response was assessed by examining changes in pump function indexes in response to 20 mg of hydralazine and in response to a dose of hydralazine titrated to decrease systemic resistance by ≥20%.

Methods

Patients: Twenty-eight patients, 15 men and 13 women, with chronic LV dysfunction were studied. All patients had a history of exertional breathlessness or fatigue, or both, during normal daily activities despite administration of digoxin and diuretics (New York Heart Association functional class III or IV). LV dysfunction was attributed to coronary artery disease in 17 patients and to idiopathic dilated cardiomyopathy in 11. The ejection fraction averaged 22 ± 8%. No patient had primary valvular disease, myocardial infarction within the previous 3 months, or worsening of their CHF within the previous 2 weeks. All patients were receiving stable doses of digoxin and furosemide and had not received any vasodilators for at least 2 weeks.

Protocol: An M-mode echocardiogram was obtained within 24 hours of hemodynamic studies using a commercially

available ultrasonoscope. The left ventricle was visualized and recorded at the high chordal level. LV end-diastolic dimension and posterior wall thickness were measured at the peak of the R wave. Echocardiograms were evaluated by one investigator without knowledge of the patient's clinical or hemodynamic status. Echocardiograms were measured with a digitizer and programmable computer. Three to 5 sequential cardiac cycles were measured and the values averaged. Relative wall thickness was calculated as 2 times the posterior wall thickness/LV end-diastolic dimension. Technically adequate echocardiograms were obtained in 26 of the 28 patients.

The following day, a thermodilution Swan-Ganz catheter was inserted and advanced to the pulmonary artery. A short polyethylene catheter was inserted into a radial artery. Duplicate baseline measurements were made of right atrial pressure, pulmonary artery pressure, pulmonary wedge pressure, and cardiac output. Cardiac output was determined in triplicate using injection of iced dextrose and a thermodilution cardiac output computer.

The response to a 20-mg dose of intravenous hydralazine was assessed in all patients. Intravenous hydralazine, 10 mg, was administered. Fifteen minutes later, an additional 10 mg was administered. Preliminary studies indicated that the peak effect of hydralazine is observed within 30 minutes after a dose. Therefore, all hemodynamic measurements were repeated 15, 30, and 40 minutes after the second dose of hydralazine. Measurements at 30 and 40 minutes were virtually identical. Therefore, measurements made at 40 minutes were used to assess the hemodynamic response to hydralazine.

The response to an effective dose of hydralazine was also assessed. An effective dose was defined as that dose which decreased systemic vascular resistance ≥20%. The effective dose was identified by administering additional 10-mg doses of intravenous hydralazine every 30 minutes until systemic vascular resistance decreased ≥20% or a total dose of 50 mg of hydralazine was achieved. Hemodynamic measurements were made at the end of each 30-minute period. The effective dose of hydralazine averaged 27 ± 7 mg (range 10 to 40). One patient had no hemodynamic response to 50 mg of intravenous hydralazine.

Calculated variables: Mean arterial pressure was determined by electronic filtration. Systemic vascular resistance (SVR) was calculated as (mean arterial pressure − mean right atrial pressure)/cardiac output. Cardiac index was calculated as cardiac output/body surface area, and stroke volume index as cardiac index/heart rate. Stroke work index (SWI) was calculated as stroke volume index · 0.0136 · (mean arterial pressure − pulmonary wedge pressure). End-diastolic LV stress was estimated as (0.334 · pulmonary wedge pressure· echocardiographic LV diastolic dimension)/[wall thickness (1 + wall thickness/LV diastolic dimension)].[5]

Statistical evaluation: All values are expressed as mean ± standard deviation. Differences between control and posthydralazine measurements were compared using Student's t test for paired data. The hemodynamic response to hydralazine was expressed as the absolute and percentage changes in SVR, cardiac output, and SWI. The relation between these responses and initial physiologic parameters was examined by linear regression analysis using the least-squares method. The following initial physiologic parameters were correlated with hemodynamic response: ejection fraction, cardiac index, stroke volume index, SWI, heart rate, systolic blood pressure, mean blood pressure, right atrial pressure, pulmonary wedge pressure, SVR, LV end-diastolic wall stress, LV diastolic dimension, and LV relative wall thickness. A p value <0.05 was considered significant.

Results

Control hemodynamic measurements revealed a mean resting cardiac index of 2.0 ± 0.5 liters/min/m^2, mean pulmonary wedge pressure of 21 ± 8 mm Hg, mean right atrial pressure of 5 ± 8 mm Hg (range 1 to 15), mean SVR of 23 ± 8 U (range 14 to 35 U), and mean LV end-diastolic dimension of 6.6 ± 1.2 cm (range 4.7 to 9.2).

Circulatory responses: Hemodynamic responses to a 20-mg dose of hydralazine and to an effective dose of hydralazine are summarized in Table I and illustrated in Figure 1. After administration of 20 mg of hydralazine, SVR decreased <20% in 10 patients, 20 to 40% in 15, and >40% in 3, indicating a variable direct vascular response to hydralazine. This vasodilation was associated with an increase in cardiac output of ≥20% in 18 patients (64%), whereas an increase in SWI of ≥20% occurred in only 10 patients (36%). Administration of an effective dose of hydralazine decreased SVR by ≥20% in all but 1 patient and increased cardiac output ≥20% in 22 of the 28 patients (79%). In contrast, the SWI increased ≥20% in only 14 patients (50%).

Determinants of the vascular response to hydralazine: To investigate factors that influence the vascular response to hydralazine, the relation between changes in SVR produced by 20 mg of hydralazine and initial physiologic variables was examined. The change in SVR correlated directly with initial SVR ($r = 0.53$) (Fig. 2). No other variable correlated with changes in SVR (Table II).

Determinants of LV pump response to vasodilation: The percentage change in SWI produced by 20 mg of hydralazine correlated directly with indexes of LV preload–end-diastolic wall stress ($r = 0.69$) and pulmonary wedge pressure ($r = 0.43$) and inversely with initial SWI ($r = -0.49$), an index of LV work (Fig. 3). The percentage change in SWI also correlated inversely with relative wall thickness ($r = -0.44$). Except for the correlation with wedge pressure, these correlations were also present when changes in SWI were expressed in absolute terms (Table II). The percentage change in SWI produced by an effective dose of hydralazine cor-

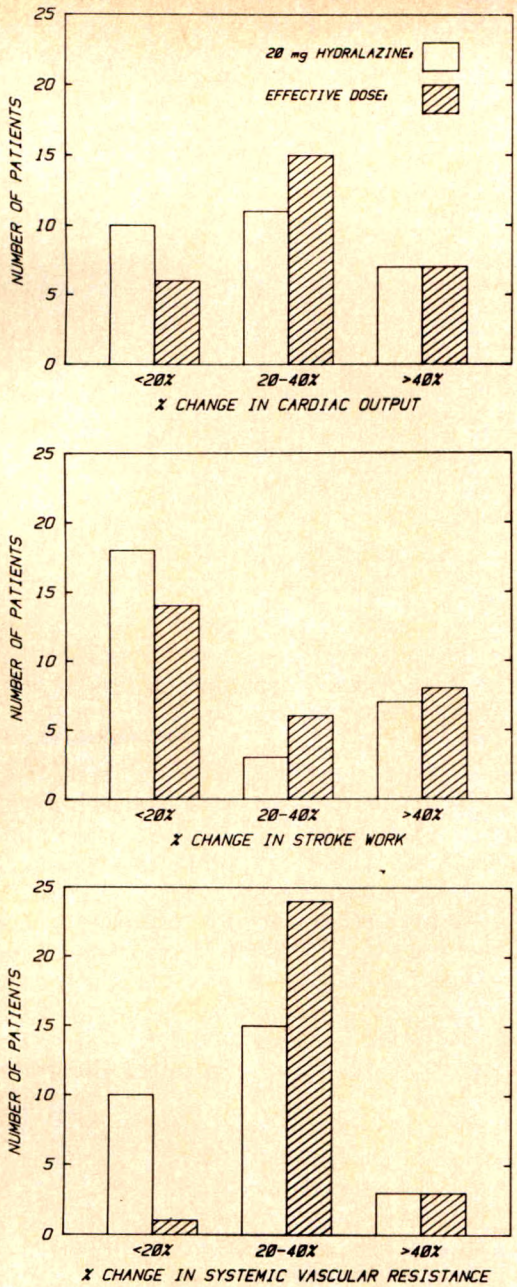

FIGURE 1. Comparison of hemodynamic responses to a 20-mg dose of intravenous hydralazine versus an effective dose of hydralazine.

related with initial SWI (r = −0.44) (Table III). The absolute change in SWI did not correlate with any measured initial physiologic parameters.

The percentage change in cardiac index produced by 20 mg of hydralazine correlated with initial end-diastolic wall stress (r = 0.48). However, this correlation was not significant when the change in cardiac index was expressed in absolute terms (Table II). The percentage change in cardiac index produced by an effective dose of hydralazine did not correlate with initial hemodynamic variables, whereas the absolute change in cardiac index correlated only with ejection fraction (r = 0.45) (Table III).

Discussion

The present study was undertaken to identify physiologic factors that account for the variable circulatory responses to hydralazine noted in patients with chronic CHF. Packer and LeJemtel[4] identified 3 factors that potentially may be responsible for this variability: (1) variations in the direct vascular effects of a drug, (2) variations in LV response to a decrease in peripheral resistance, and (3) variations in the degree to which

peripheral vasodilation activates endogenous neurohumoral mechanisms. Accordingly, it is of interest to examine how initial physiologic parameters measured in this study influenced each of these 3 factors.

Determinants of direct vascular response to hydralazine: Vascular responsiveness to hydralazine may be assessed by examining the degree to which a fixed dose of hydralazine alters peripheral vascular resistance. Using this approach, our results indicate that direct vascular responses to hydralazine are quite variable. After a 20-mg dose of hydralazine, 18 patients exhibited a ≥20% decrease in SVR, whereas 10 patients had a <20% decrease.

The only physiologic factor that correlated with the direct vascular effect of hydralazine was initial SVR; the degree to which hydralazine decreased SVR was directly related to initial SVR. This finding is consistent with experimental studies which demonstrated that the magnitude of vasodilation produced by a given stimulus is a linear function of the resistance before stimulation.[6,7]

Recently, it has been suggested that venous pressure also may influence vascular responsiveness to hydralazine[2]; the dose of oral hydralazine required to produce vasodilation correlated inversely with right atrial pressure. In the present study, no relation between vascular response to hydralazine and right atrial pressure was noted. Therefore, it is likely that venous pressure correlates with the hemodynamic response to oral hydralazine because of an association with drug absorption rather than vascular responsiveness.

Determinants of LV pump response to vasodilation: There are several ways to examine the LV pump response to peripheral vasodilation. The pump response to a fixed dose of hydralazine can be examined. Alternatively, the pump response to a dose of hydralazine that produces a given degree of peripheral vasodilation can be examined.

Our findings indicate that regardless of which of these 2 approaches is used, the LV pump response to peripheral vasodilation varies widely. Our findings further suggest that the response may be related to the initial level of LV pump dysfunction. Changes in SWI after 20 mg of hydralazine were directly related to indexes of LV preload, end-diastolic wall stress and pulmonary wedge pressure, and inversely related to SWI, an index of cardiac systolic performance. Thus, patients with the most severe cardiac dysfunction as evidenced by high preload and low systolic performance tended to respond most favorably to vasodilation. Less close correlations between physiologic variables and hemodynamic responses were noted after an effective dose of hydralazine, although the findings were generally consistent with this conclusion.

Correlations between initial hemodynamic parameters and the response to hydralazine, however, were not sufficiently close to provide clinically useful predictive information about an individual patient's response to hydralazine. Moreover, several of these correlations were between an initial parameter and a change in that parameter. Because the initial parameter influences the calculation of the change, such correlations involve

dependent variables and thus must be interpreted cautiously. Therefore, it is likely that the response to hydralazine is not a simple function of 1 circulatory factor. This finding is not unexpected because the coupling between the peripheral circulation and LV afterload is complex. For example, a given perturbation in systemic resistance may have different effects on central blood pressure and, therefore, on LV afterload depending on arterial impedance and baroreceptor activity.

In contrast to our findings, Packer et al[2] noted a relatively close linear correlation between the hemodynamic response to an effective dose of hydralazine and initial LV end-diastolic dimension. LV end-diastolic dimension is an important determinant of LV wall stress, whereas left ventricles with high wall stress are more sensitive to afterload manipulation.[8] Accordingly, these investigators suggested that LV diastolic dimension influences LV pump response to vasodilation due to its relation to wall stress.

The findings of Packer et al[2] are not necessarily inconsistent with our results. Packer et al induced more marked vasodilation in their patients, as evidenced by average decreases in mean arterial pressure of 9 mm Hg in patients with LV end-diastolic dimensions >6 cm and of 16 mm Hg in those with dimensions ≤6.0 cm. In addition, the average SVR after hydralazine was 12.5 U, versus 15 to 18 U in the present study. It is possible that when vasodilation is moderate, as in the present study, LV end-diastolic dimension does not correlate with hemodynamic response. However, when more marked vasodilation is produced, LV end-diastolic dimension does correlate with hemodynamic response.

In any event, the degree of arterial pressure reduction produced in the study of Packer et al[2] is usually not tolerated by patients with CHF due to orthostatic dizziness. Moreover, such reduction in arterial pressure may activate endogenous neurohumoral mechanisms that counteract potentially beneficial hemodynamic effects.[9] Therefore, hydralazine is usually administered clinically in doses that do not produce marked reductions in arterial pressure.[10,11] Our data suggest that LV end-diastolic dimension is not a useful predictor of a patient's hemodynamic response to such dosages.

Hemodynamic response to hydralazine and neurohumoral activation: The degree to which hydralazine activates endogenous neurohumoral mechanisms was not specifically examined in this study. However, it is likely that the degree of activation was modest, if present at all, because mean blood pressure decreased only slightly and no substantial increases in heart rate were observed.

Clinical importance of assessing circulatory response to hydralazine: The clinical importance of identifying the degree of hemodynamic response to hydralazine remains uncertain; a correlation between acute hemodynamic response and long-term clinical response has been observed by some investigators[2,3] but not by others.[12] However, there is agreement that patients who exhibit no acute improvement in pump function with hydralazine usually have no long-term clinical improvement.[2,3,12] Therefore, at the very least, identification of factors that characterize nonresponders to hydralazine is of clinical interest.

Clinical implications: This study indicates that both the direct vascular and the LV pump response to hydralazine is extremely variable in patients with heart failure. Therefore, patients with clinical CHF represent a very heterogeneous population with respect to both their peripheral vasculature and the manner in which the peripheral vasculature is coupled with the left ventricle. This heterogeneity may account for some variability in clinical response to long-term vasodilator therapy.

Our findings further suggest that patients with the highest initial peripheral vascular resistance and most severe pump dysfunction are most likely to exhibit a favorable acute hemodynamic response to moderate doses of hydralazine. However, no correlations between hemodynamic responses and initial physiologic variables were sufficiently close to serve as useful clinical predictors of an individual patient's circulatory response to hydralazine. Therefore, in patients with chronic CHF, initiation of hydralazine should probably be performed in conjunction with hemodynamic monitoring to assure that a patient is responsive to hydralazine. If a patient does not respond acutely to hydralazine, another vasodilator should probably be used instead.

Amrinone Therapy for Congestive Heart Failure in Outpatients With Idiopathic Dilated Cardiomyopathy

CARL V. LEIER, MD, KAREN DALPIAZ, RN, PATRICIA HUSS, RN, JAMES B. HERMILLER, MD, RAYMOND D. MAGORIEN, MD, THOMAS M. BASHORE, MD, and DONALD V. UNVERFERTH, MD

Amrinone, 100 mg orally every 8 hours, was administered to 13 patients with moderate-to-severe congestive heart failure (CHF) for 1 month on an outpatient basis to determine the beneficial and undesirable effects of this new cardioactive agent in this clinical setting. These subjects received conventional CHF medications during the course of study. Ten patients who received conventional CHF medications alone served as a control group. Changes in functional classification were not significantly different between the 2 treatment groups. Amrinone augmented exercise capacity 37% above baseline compared with a 12% improvement for the control group. Noninvasive indexes of resting left ventricular function (echocardiography and systolic time intervals) did not change significantly for either group, nor was there a significant change in the exercise ejection fraction. All patients treated with amrinone had ≥1 symptom-related or laboratory-detected adverse effect. An increase in the frequency of ventricular ectopic beats was noted at rest in 4 and with exercise in 6 patients (salvos of nonsustained ventricular tachycardia in 2). Six subjects treated with amrinone had gastrointestinal symptoms and 8 developed a viral-like illness. Other adverse effects noted in the amrinone-treated group included near-syncope, headaches, marked anxiety, chest pain, palpitations, maculopapular rash, hypokalemia, and elevation of serum transaminase levels. The control patients had significantly fewer adverse effects.

Although individual patients with CHF may benefit from long-term amrinone therapy, the low benefit-to-risk–adverse effect ratio does not warrant widespread application of this drug in the outpatient management of CHF and requires caution when prescribing.

The therapy of chronic, low-output congestive heart failure (CHF) is a formidable clinical problem. The treatment of CHF is generally directed at reducing congestion (diuretics and preload-reducing vasodilators) and augmenting cardiac output (inotropic agents and afterload-reducing vasodilators). Digitalis is the only drug used on a long-term basis for its positive inotropic properties, but its effectiveness and safety remain controversial. A more effective nonparenteral positive inotropic drug would play an important role in the management of low-output CHF. Amrinone was developed to fulfill this need.[1,2] Initial studies[3–9] of amrinone in patients with CHF suggest that this compound improves resting and exercise hemodynamic findings. This study was designed to determine the beneficial properties and adverse effects of amrinone in the outpatient management of CHF.

Methods

Patients: Twenty-four patients with catheterization-proved idiopathic dilated cardiomyopathy and CHF of moderate severity were studied. These patients were separated into 2 groups: a group of 14 patients who were treated with amrinone while continuing conventional CHF therapy, and a randomly assigned control group of 10 patients who received conventional CHF therapy alone. One patient from the amrinone group had clinical deterioration within 2 weeks of entry and had to be withdrawn from the study and analysis. The clinical characteristics of the remaining 13 amrinone-treated patients and the 10 control patients are presented in Table I. There were no significant differences between the 2 groups in age, sex, or duration and severity of CHF. There was no significant difference in the conventional CHF therapy (drugs and dosage) of the 2 groups.

Protocol: The study was performed in the Human Heart Failure Research Laboratory of the Ohio State University

Outpatient Clinic. Baseline studies included clinical evaluation (history and physical examination) by 1 of the clinical investigators (CVL or DVU), hematologic and blood chemistry testing, M-mode echocardiography, systolic time intervals, treadmill exercise testing, and resting and exercise radionuclide angiography.

The patients of the amrinone group then began taking ora amrinone, 100 mg every 8 hours, along with the continuatior of their maintenance conventional CHF therapy. The contro patients continued their conventional therapy. The patient returned to the laboratory on a weekly basis for clinical eval uation, symptom and drug recording, and pill counts. Digitali preparations, vasodilators, and doses thereof were not altere during the course of study. Diuretic doses were adjusted ir response to clinical indications (symptoms, physical signs weight). At the end of the 4-week treatment period, eac participant underwent the same studies as those at baseline with cardiac and exercise testing performed 2 hours afte amrinone dosing.

Procedures and measurements: M-mode echocardiog raphy and systolic time intervals were performed with ar Electronics for Medicine Echo IV unit using the technica specifications previously described.[10–12] The echocardio graphic determinants[10,11] of left ventricular (LV) performanc included fractional shortening (% ΔD) and fractional short ening rate (Vcf). The ratio of the preejection period to LV ejection time (PEP/LVET) was used as the systolic time in tervals parameter of LV function.[12]

Treadmill exercise testing, using an Avionics Del Mar 59 treadmill interphased with a Sanborn Hewlett-Packar Visoscope and recorder, was performed in duplicate; th second treadmill was used for baseline data. A modifie Naughton protocol was used for graded exercise testing wit increments in grade, speed, or both occurring every 2 minute 0% 1 mph, 0% 1.5 mph, 3.5% 2 mph, 7% 2 mph, 10.5% 3 mp and 12.5% 3 mph. Fifteen-minute electrocardiographic re

TABLE II Clinical Responses of the 2 Treatment Groups to 4 Weeks of Therapy

	Amrinone Group (n = 13)	Control Group (n = 10)
Functional classification (no. of patients)		
Improvment by ≥1 class	5	3
No change	7	5
Deterioration by ≥1 class	1*	2

Headaches	2	0
Near syncope	4	1
Onset of persistent anxiety with tremors	2	0
Maculopapular rash	1	0
Laboratory abnormalities		
Mean change (±1 standard deviation) in platelet count/mm³ at 1 month	−33,500 ± 38,000†‡	+5,000 ± 17,000
Abnormal elevation of SGOT	1 patient (26 → 178)	0
Severe hypokalemia (≤3.0 mEq/liter)	1‖	0

* An additional patient was dropped from the study and analysis because of marked deterioration of cardiac function and subsequent prolonge hospitalization.
† $p < 0.05$ (amrinone versus control).
‡ $p < 0.05$ (versus baseline).
§ Two of these subjects also had salvoes of ventricular tachycardia (≥3 beats in series) and one patient had frequent paroxysms (duration ≥20 seconds) of supraventricular tachycardia.
‖ This participant required hospitalization for hypokalemia (2.6 mEq/liter) and her first episode of sustained supraventricular tachycardia.
SGOT = serum glutamic oxaloacetic transaminase.

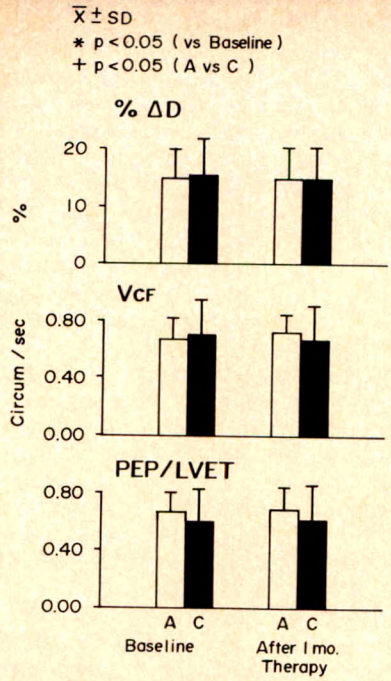

FIGURE 1. Results of echocardiographic (% ΔD and Vcf) and systolic time interval (PEP/LVET) testing at baseline and after 1 month of amrinone (plus conventional therapy) treatment (A) or conventional therapy alone (control group, C). % ΔD = fractional shortening; PEP/LVET = ratio of preejection period to left ventricular ejection time; Vcf = fractional shortening rate.

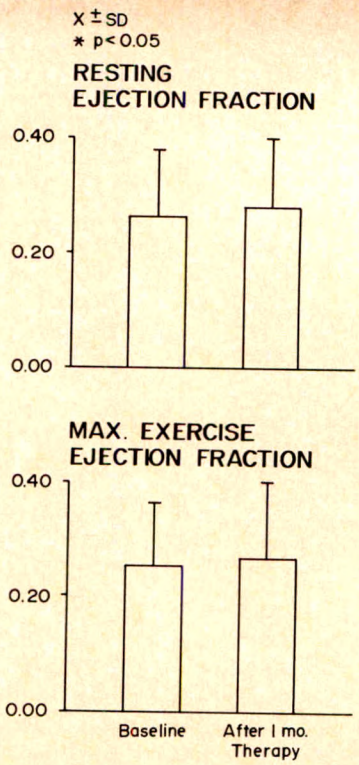

FIGURE 2. Left ventricular ejection fraction, measured at rest (**top**) and at maximal (Max) exercise (**bottom**), did not change significantly after 1 month of amrinone (plus conventional therapy). The ejection fraction was determined by multiple-gated radionuclide angiography.

cordings were obtained before exercise and were continued throughout the exercise period for the determination of heart rate and frequency of ventricular ectopic beats. Maximum exercise capacity was the time at which exercise was stopped because of severe dyspnea or fatigue (symptom-limited maximal exercise) or both.

Exercise radionuclide (technetium-99m pertechnetate) angiography was performed in a standard manner with a Picker Dyna-Mo gamma camera, a Medical Data A^2 40,000 computer system, and a Quinton Uniwork supine bicycle ergometer. Beginning at a work load of 150 kg-m/min, exercise was accomplished in a stepwise fashion with work load increments of 150 kg-m/min every 2 minutes. At maximal exercise, 1 minute of exercise was required before the 2-minute acquisition. The number of radionuclide studies for the control group was insufficient for analysis and therefore were not included.

All technical personnel performing the noninvasive and exercise studies were blinded with respect to treatment. Because it was necessary to adjust and maximize amrinone dosage, the physicians responsible for the clinical care of these patients were not blinded.

Statistical analyses: The clinical and laboratory characteristics of the 2 groups were compared using the Student *t* test for unpaired data and chi-square analysis. Changes within a group between baseline and the 4-week data were analyzed with the Student *t* test for paired data.

Results

Noninvasive cardiac studies and exercise testing: The echocardiographic measurements of LV function (% ΔD and Vcf), the PEP/LVET, and the resting ejection fraction by radionuclide angiography did not change significantly over 1 month of therapy for either group (Fig. 1 and 2).

Four weeks of amrinone therapy effected a significant increase (37%) in maximal exercise capacity above baseline and above that of the parallel control group (12%) (Fig. 3). Heart rate at maximal exercise increased significantly for the amrinone group and averaged +14% above baseline; the control group had little difference in maximal exercise heart rate between baseline and 1-month testing. Changes in mean exercise duration and mean heart rate during bicycle exercise–radionuclide angiography were comparable to those noted during treadmill testing. LV ejection fraction at maximum exercise did not change significantly for the amrinone group after 1 month of treatment (Fig. 2, bottom panel).

Clinical responses (Table II): Five patients of the amrinone group and 3 control patients improved 1 functional classification during the 1-month treatment period. One patient receiving amrinone and 2 control subjects had a deterioration in clinical status. An additional patient was dropped from the amrinone group 10 days after entry because of marked deterioration in his CHF status (pulmonary edema, adult respiratory distress syndrome, and 2 cardiac arrests); improvement coincided with discontinuation of amrinone and the initiation of appropriate supportive measures.

Mean body weight increased 1.14 kg ($p < 0.05$ versus baseline) over the 4-week period for the control group despite an increase in mean furosemide dosage of 39 ± 46 mg. The increase in body weight for the control group was significantly greater than the mean weight change of the amrinone group (−0.61 kg). Mean diuretic dosage

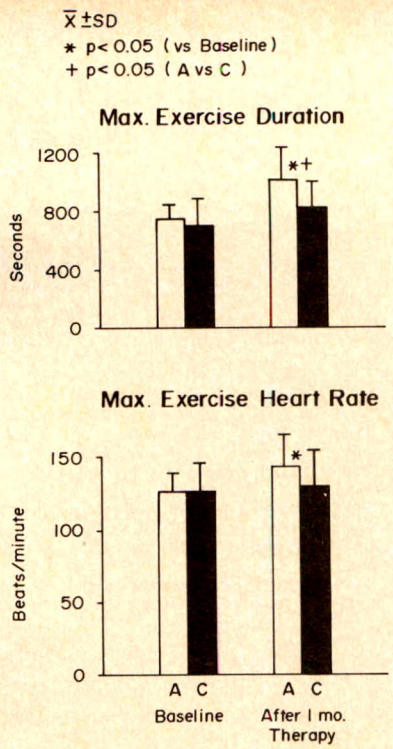

FIGURE 3. Results of treadmill testing for the amrinone (plus conventional therapy) treatment group (A) and the conventional therapy control group (C). Max = maximal.

for the amrinone-treated subjects was not altered during the 1-month course of therapy (1 patient required an increase of 40 mg/day of furosemide; another required a decrease of 40 mg/day).

Resting heart rate for the amrinone group increased significantly above baseline and above that of the control group. Resting mean systemic arterial pressure was not altered for either group.

Four patients of the amrinone group had a documented increase in ventricular ectopic beats (≥4 beats/min) at rest; these patients and 2 others also had an increase in ectopic beats during exercise testing. The exercise study at 1 month was interrupted in 2 subjects treated with amrinone because of short bursts of ventricular tachycardia. In 1 patient, frequent paroxysms of supraventricular tachycardia developed during exercise testing. Another patient, who had no history of cardiac arrhythmia, had hypokalemia (serum potassium level 2.6 mEq/liter) and sustained supraventricular tachycardia within 1 week of initiating amrinone. She had no recurrence of the dysrhythmia after the hypokalemia was corrected despite the continuation of amrinone.

Six patients of the amrinone-treated group complained of gastrointestinal symptoms and 8 had a viral-influenza-like illness. These symptoms lasted 1 to 4 weeks and were treated symptomatically without interrupting amrinone administration. Four of the 6 patients who had gastrointestinal complaints and 4 of 8 who had the viral-like illness during amrinone therapy had a gradual amelioration of these adverse effects by the fourth week. Other symptoms noted during amrinone therapy were palpitations, chest pain, headaches, near-syncope (lightheadedness, dizziness, and blurred vision), persistent marked anxiety, maculopapular rash, and night sweats. Adverse effects were considerably less frequent in the control group.

The mean platelet count decreased by 33,500 platelets/mm^3 ($p < 0.05$) after 1 month of amrinone treatment. The actual nadir in the platelet count generally occurred 1 to 3 weeks after initiation of amrinone therapy and typically returned toward baseline thereafter. The count never dropped below 105,000 platelets/mm^3 for any subject. No evidence of excessive bruising or bleeding occurred during the study period. The serum glutamic oxaloacetic transaminase level increased 7-fold in 1 amrinone-treated patient and returned to baseline within 2 weeks after discontinuing amrinone.

Despite the occurrence of adverse effects, amrinone was continued for 4 weeks in all but 1 patient. At the end of the 4 weeks, 3 more patients were removed from a more long-term phase of amrinone therapy. One of these patients had elevated serum transaminase levels, anxiety and tremors, ventricular ectopic beats at rest, and salvos of ventricular tachycardia during exercise. He had had no ventricular ectopy before amrinone administration and the ectopic beats and exercise-induced ventricular tachycardia abated, as did the elevated transaminase levels, upon stopping amrinone. Amrinone was discontinued in another patient who had chest pain, palpitations, and frequent ventricular and atrial ectopic beats at rest and during exercise; the events abated after amrinone was stopped. The third patient had a viral-like illness, excessive fatigue, and marked dyspnea with amrinone; he improved when the drug was stopped.

Discussion

This study has demonstrated that the addition of standard chronic dosing of amrinone to conventional CHF therapy augments exercise capacity above baseline and above that achieved by patients who receive conventional therapy alone. Whether this improvement in exercise tolerance is maintained beyond 4 weeks is under investigation. The reasons for increased exercise capacity with amrinone are not explained by this study. LV ejection fraction during exercise and the noninvasive indexes of ventricular function, performed at rest, were not improved with chronic amrinone therapy. Increased effort was probably contributory, particularly since heart rate at maximum exercise was higher at 4 weeks.

The patients treated with amrinone also maintained a constant body weight and diuretic dosage compared with the control group who, despite an increase in mean diuretic dosage, gained an average of approximately 1 kg over the 1-month study period. There was no significant difference between the 2 groups in the percentage of patients having improvement, no change, or clinical deterioration. It is unlikely that the lack of dramatic clinical and laboratory improvement with amrinone (plus conventional therapy) was secondary to inadequate dosage, since each of the amrinone-treated subjects experienced 1 or more adverse effects attributable to this agent.

The rather limited beneficial effects of amrinone in our patients with CHF were offset by the frequent occurrence of adverse effects. A high frequency of adverse effects with amrinone was also noted in 5 patients with moderate CHF studied by Dunkman et al.[13] While patients with CHF may have more cardiac and noncardiac symptoms compared with normal human subjects, our study clearly demonstrates that the addition of amrinone to conventional therapy elicits a significant and marked increase in undesirable effects involving the cardiovascular, neurologic, gastrointestinal, hematologic, and dermatologic systems. Thrombocytopenia, a major adverse effect noted previously[5,9] at higher doses of amrinone, was not a major problem during amrinone administration in this study.

How amrinone improves hemodynamic features in CHF is not well understood. Similarly, the mechanisms for the numerous adverse effects are not known. Based upon the high incidence and spectrum of symptom- and laboratory-related adverse effects, it is obvious that amrinone's pharmacologic effects are not confined to the heart or the cardiovascular system. This agent apparently alters the physiology and, in some instances, the biochemistry of several organ systems.

The overall efficacy of continuous amrinone therapy was limited in our patients as a group, and none of the patients had dramatic individual improvement. The frequency of clinical and laboratory adverse effects was high and some were potentially lethal. It is unlikely that amrinone will be widely used in the therapy of CHF.

DEL MAR AVIONICS

This tiny chip is a big reason why the Trendsetter® II System analyzes ambulatory ECG data so precisely.

Advanced electronics, capable of processing more than 5 million instructions per second, make the Trendsetter II design concept the most thorough approach ever developed to scan Holter tapes.

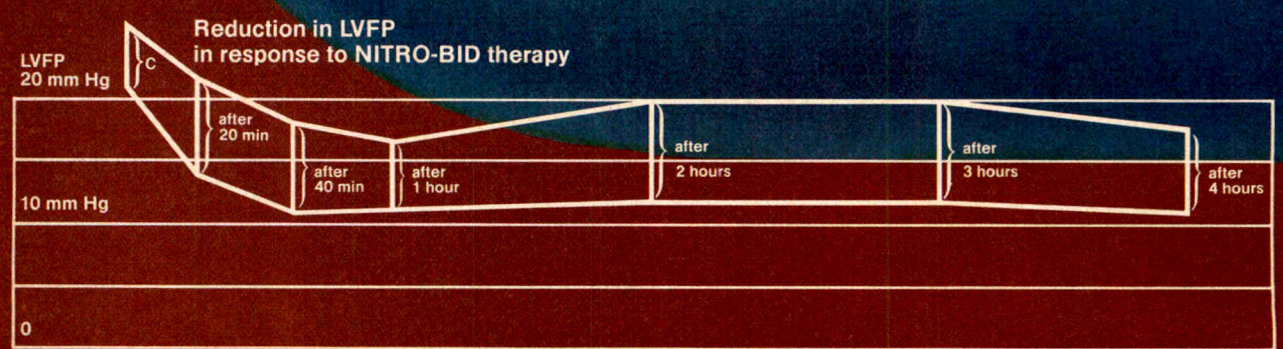
Accurate arrhythmia analysis is accomplished by morphology comparison, using variable, patient specific analysis parameters. These include bradycardia rate and interval; pause interval; T-wave amplitude; V-tach minimum rate; SVE minimum rate and prematurity; and selectable R-on-T adjustments for intrinsic heart rate variations. You get accurate and verifiable results on all patients — from pediatric to adult.

Additionally, arrhythmia analysis is enhanced by dedicated circuitry for manipulating artifactual data. Artifact can either be recognized and classified, or be deleted from analysis. So there's no artifact distortion.

The Trendsetter II System also features Express Trac,™ an advanced method of instantly analyzing and quantifying significant arrhythmia with no operator intervention.

For more details on the Holter system designed with your precise patient needs in mind, contact Del Mar Avionics, 1601 Alton Avenue, Irvine, CA 92714 (714) 549-1500, Telex 68-31110 or 68-5621.

DYNAMIC



plus a dosage range for most angina* patients in your practice

"...objective evidence of the... hemodynamic effects of ONTG [oral nitroglycerin].... [shows] LVFP [left ventricular filling pressure] was significantly reduced from 23 mm Hg to 17 mm Hg ($p<0.01$) 20 min after administration of ONTG and this effect persisted over the entire four hours...."†[1]

"After the administration of sustained-release nitroglycerine, peak effects were seen in about 2 hours. However significant effects were still seen at 4 and 6 hours in most patients."[2]

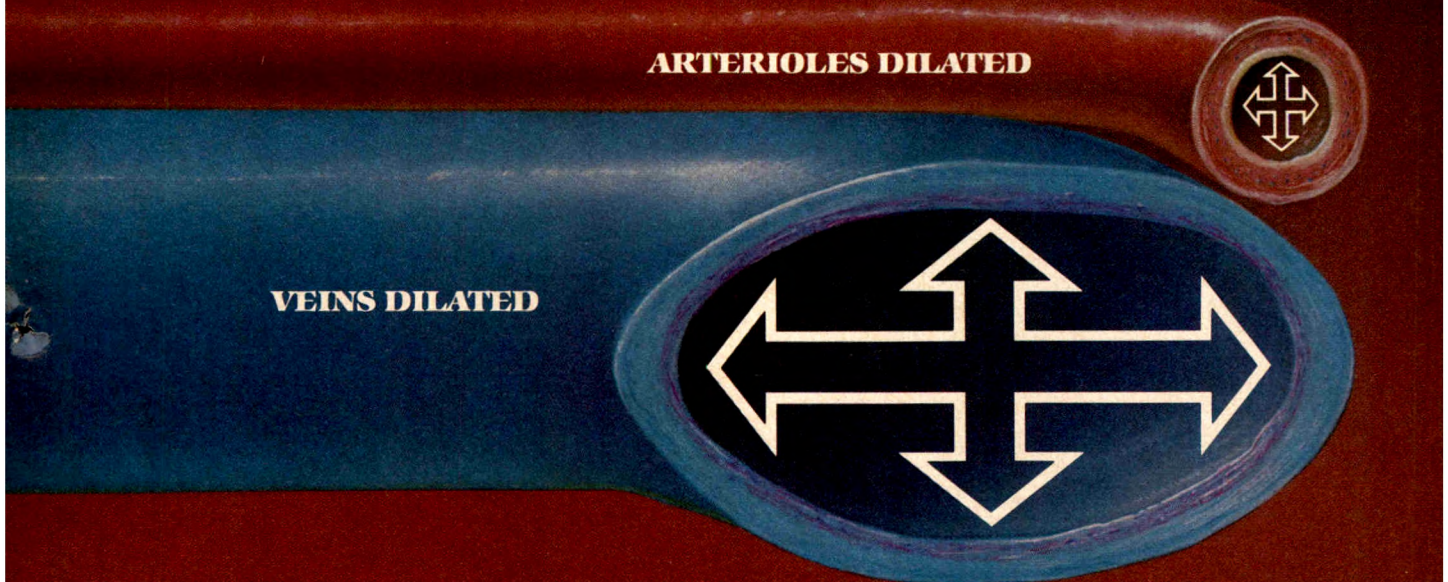
Nitro-Bid Capsules are available in three dosage strengths to meet the needs of most angina patients and to help return each patient to a more normal life.

NITRO-BID® Capsules
(nitroglycerin)
9mg, 6.5mg, 2.5mg

* This product has been evaluated as possibly effective for this indication. See Professional Use Information.

†Although the reduction in hemodynamic effects continued for more than four hours, the study was discontinued after that period of time.

HEMODYNAMIC RESPONSE



NITRO-BID® Capsules (nitroglycerin) 9mg, 6.5mg, 2.5mg

Professional Use Information

NITRO-BID® CAPSULES (nitroglycerin)

* **INDICATIONS:** Based on a review of this drug and a related drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective:
For the management, prophylaxis or treatment of anginal attacks. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS: Acute or recent myocardial infarction, severe anemia, closed-angle glaucoma, postural hypotension, increased intracranial pressure, and idiosyncrasy to the drug.

WARNINGS: Capsules must be swallowed, FOR ORAL, NOT SUBLINGUAL, USE. NITRO-BID® 2.5, NITRO-BID® 6.5, and NITRO-BID® 9 Controlled-Release Capsules are not intended for immediate relief of anginal attacks.

PRECAUTIONS: Intraocular pressure may be increased; therefore, caution is required in administering to patients with glaucoma. Tolerance to this drug and cross-tolerance to other organic nitrites and nitrates may occur. If blurring of vision, dryness of mouth, or lack of benefit occurs, the drug should be discontinued.

ADVERSE REACTIONS: Severe and persistent headaches, cutaneous flushing, dizziness and weakness. Occasionally, drug rash or exfoliative dermatitis and nausea and vomiting may occur; these responses may disappear with a decrease in dosage. Adverse effects are enhanced by ingestion of alcohol, which appears to increase absorption from the gastrointestinal tract.

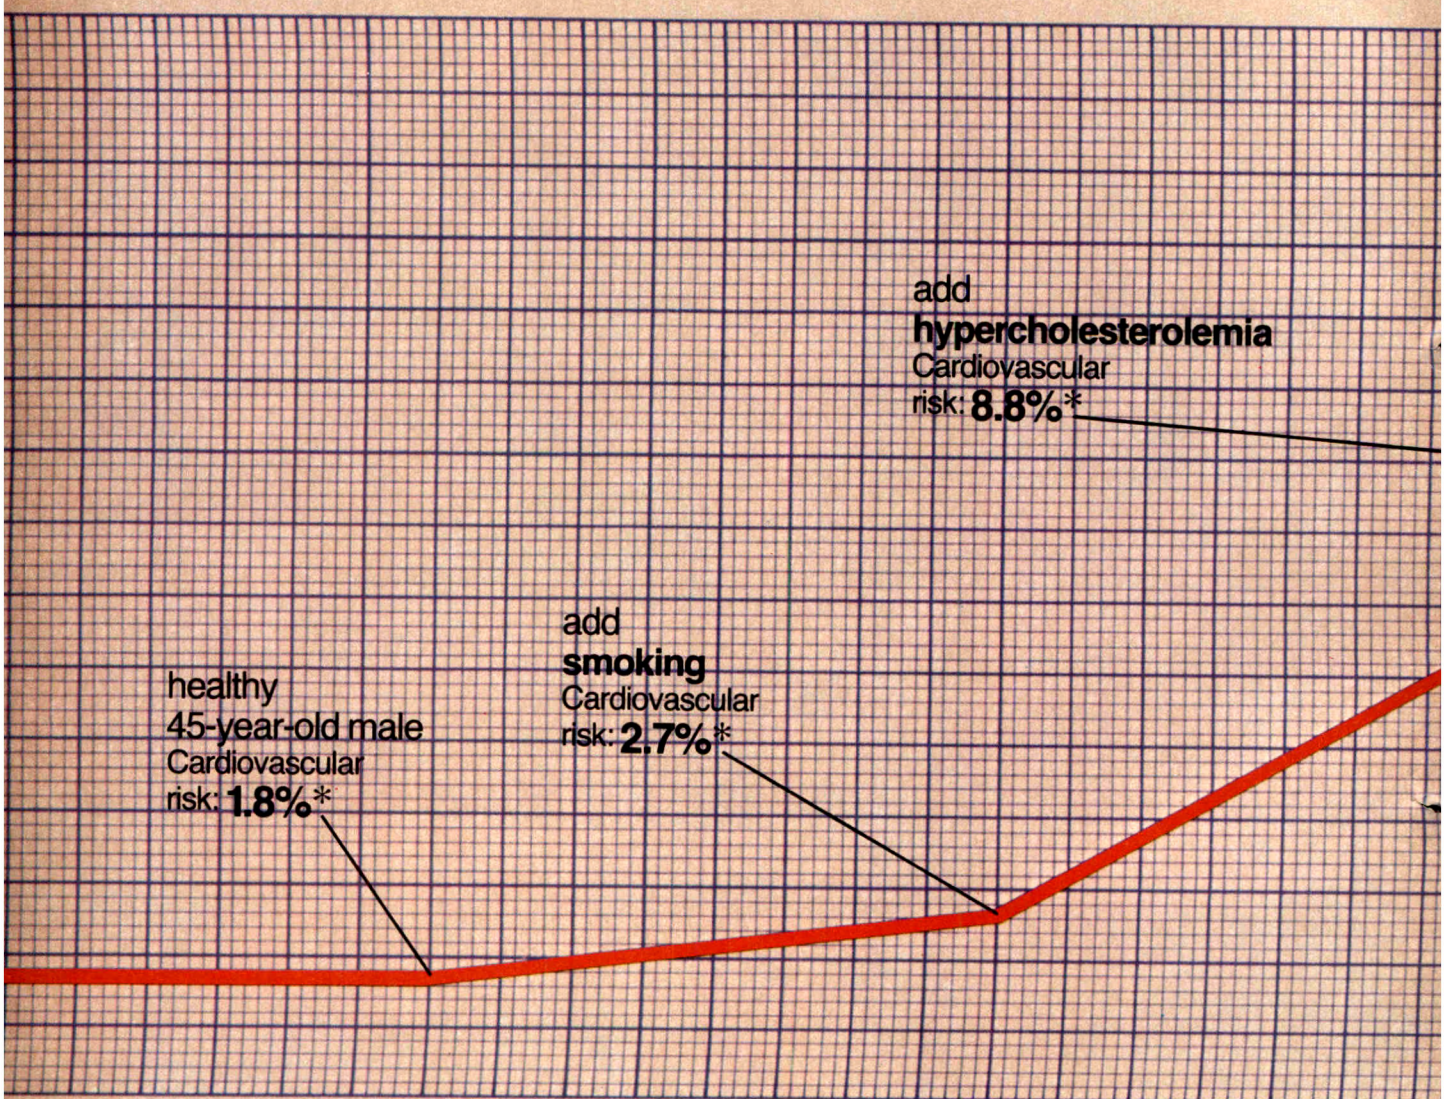
MARION LABORATORIES, INC.
KANSAS CITY, MO. 64137

In hypertensive patients:

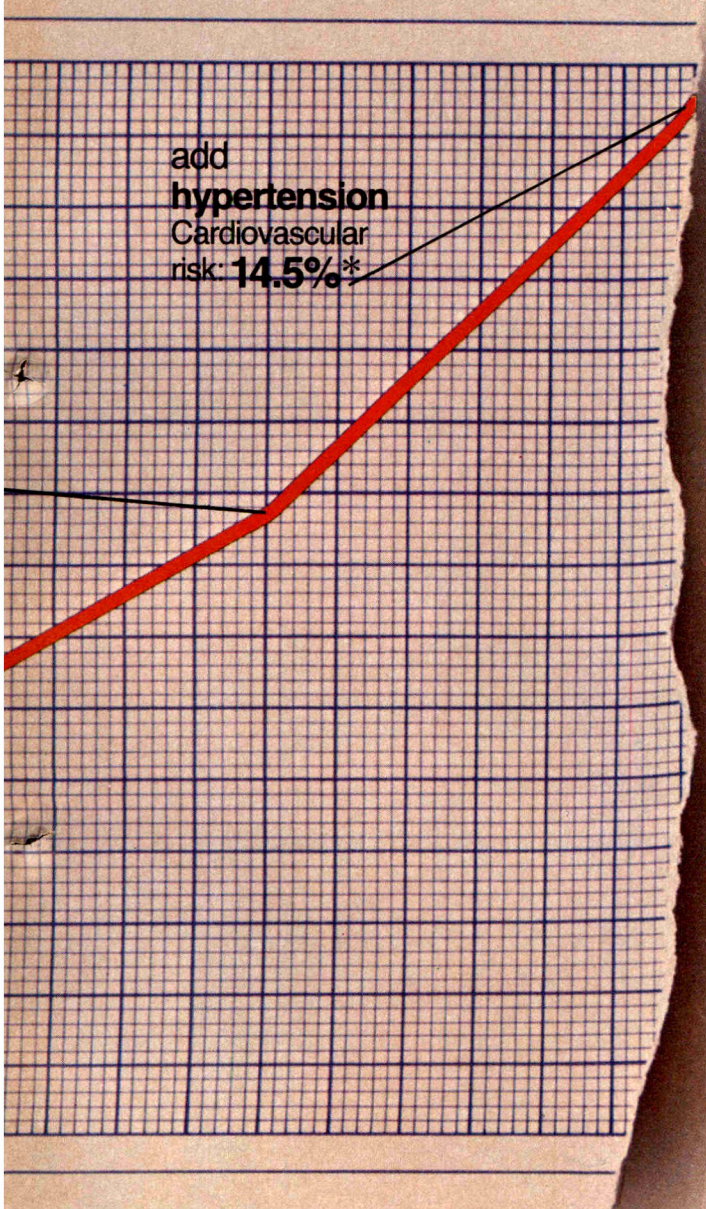


Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

Consider the Risks



▪ When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

▪ Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

▪ Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

Please see Minipress brief summary on following page.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

Minipress® (prazosin HCl) Capsules 1 mg, 2 mg, 5 mg **B.I.D. Dosage Convenience**

BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*
INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.
If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.
Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.
More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.
Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.
ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.
The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)
Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.
Cardiovascular: edema, dyspnea, syncope, tachycardia.
Central Nervous System: nervousness, vertigo, depression, paresthesia.
Dermatologic: rash, pruritus, alopecia, lichen planus.
Genitourinary: urinary frequency, incontinence, impotence, priapism.
EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.
Other: diaphoresis.
Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.
In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.
DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:
Initial Dose: 1 mg two or three times a day. (See Warnings.)
Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.
Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.
HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

Echocardiographic Evaluation of Porcine Bioprosthetic Valves: Experience With 309 Normal and 59 Dysfunctioning Valves

MOHSIN ALAM, MD, JEFFREY B. LAKIER, MD, SOL D. PICKARD, MD, and SIDNEY GOLDSTEIN, MD

To determine the clinical value of echocardiographic evaluation of porcine bioprosthetic valves, the findings in all patients who had porcine bioprosthetic valve replacement and adequate quality echocardiographic studies from 1978 to 1982 were analyzed. The study includes 309 normal and 59 dysfunctioning valves. Valve dysfunction resulted from spontaneous cusp degeneration in 39 (34 valve regurgitations, 5 stenoses), infective endocarditis in 12, paravalvular regurgitation in 5, regurgitation of redundant cusps, mitral valve thrombi, and aortic stent stenosis in 3 others. Echocardiographic findings were correlated with gross surgical pathologic or autopsy findings in 45 of the 59 dysfunctioning valves. Echocardiographic abnormalities were demonstrated in 41 of 59 (69%) dysfunctioning valves. A systolic mitral or diastolic aortic valve flutter was diagnostic of a regurgitant valve caused by a torn or unsupported cusp margin and was observed in 28 of 34 (82%) regurgitant valves with no false-positive studies. Echocardiographic cusp thickness of ≥3 mm correctly identified all regurgitant and stenotic valves with gross anatomic evidence of localized or generalized cusp thickening or calcific deposits. Echocardiographic valve abnormalities were observed in only 4 of 12 patients with infective endocarditis and in 1 of 5 with paravalvular regurgitation.

Thus, echocardiography provides important information regarding the function of porcine bioprosthetic valves and is of value in the decision to replace these valves, especially when dysfunction is due to spontaneous cuspal degeneration. Echocardiography is neither sensitive nor specific in patients with infective endocarditis and paravalvular regurgitation.

The stent-mounted, glutaraldehyde-fixed porcine bioprosthetic aortic valve has become one of the major prosthetic valves currently in use.[1–5] Although these valves have good hemodynamic features and a low rate of thromboembolism, dysfunction due to cusp degeneration can occur. The valve may also become infected, develop thrombus on its surface, or sustain nonleaflet structural changes.[6–10] Recognition of complications is important for prompt initiation of appropriate medical and surgical therapy. It is also important to establish normal function of the valve in the setting of changing symptoms or a deteriorating clinical state. Echocardiography has been beneficial in establishing normal as well as abnormal function of all prosthetic valves,[11–13] and particularly the porcine bioprosthesis.[14–23] This study reports our echocardiographic experience with normal and abnormal porcine bioprosthetic valves and provides information that may assist in differentiating the various forms of valve dysfunction.

From the Department of Medicine and the Division of Cardiovascular Medicine, Henry Ford Hospital, Detroit, Michigan. Manuscript received January 5, 1983; revised manuscript received May 5, 1983, accepted May 6, 1983.

Address for reprints: Mohsin Alam, MD, 2799 West Grand Boulevard, Henry Ford Hospital, Detroit, Michigan 48202.

Methods

Of 424 echocardiographic studies of porcine bioprosthetic valves (Hancock and Carpentier-Edwards) performed in our laboratory between 1978 and 1982, 368 (89%) were technically adequate, as defined by the echocardiographic demonstration of ≥1 of the 3 cusps of the heterograft valve.

All M-mode echocardiographic studies were performed from the left parasternal approach using commercially available instruments. The valve cusps were differentiated from the echocardiographic reflective stents by recording their opening and closing motion. The cusps, once visualized, were expanded and slowly scanned for abnormal motion or flutter and records taken at 50 or 100 mm/s paper speed. The maximum thickness of the valve was measured from enlarged recordings in the closed position, that is, during systole in the mitral position and during diastole in the aortic position.

TABLE I Clinical Characteristics of Valve Dysfunction

	Valves (n)	Echocardiographic Valve Abnormalities	
		n	%
Spontaneous degeneration	39	33	85
Valvular regurgitation (34		28	82
Valvular stenosis (5)		5	100
Bacterial endocarditis	12	4	33
Paravalvular regurgitation	5	1	20
Redundant aortic valve	1	1	100
Aortic stent stenosis	1	1	100
Valve thrombus (probable)	1	1	100
Total	59	41	69

Great care was taken not to influence the valve thickness by using a high-gain or a low-reject setting, or both. Whenever possible, the initial diastolic slope and systolic excursion of the anterior stent of the mitral valve and the maximal systolic cusp opening and internal stent dimensions of the aortic valve were measured.[14,15]

Adequate-quality 2-dimensional (2-D) echocardiographic studies were also available for analysis in 79 normal and 38 dysfunctioning valves. All 2-D studies were evaluated in the parasternal long and short axis and, recently, apical 4-chamber views.

Results

During the 4 years of study, 309 of the 368 valves were adjudged normal clinically and echocardiographically. In this normal group, 203 valves were implanted in the mitral, 101 in the aortic, and 5 in the tricuspid location. The remaining 59 patients exhibited clinical deterioration or infection with valvular stenosis, regurgitation, or death resulting from valve dysfunction. In 41 (69%) of these, the valve abnormality was detected by echocardiography (Table I). In this abnormal group, 35 valves were implanted in the mitral, 22 in the aortic, and 2 in the tricuspid position.

Normal function: M-mode echocardiograms of normal porcine bioprosthetic valves in the aortic, tricuspid, and mitral position are shown in Figure 1. The systolic opening of the aortic valves ranged from 10 to 24 mm and the internal stent diameter from 15 to 25 mm. The range of the initial diastolic stent slope of the mitral valves was 4 to 33 mm/s and the systolic excursion of the anterior stent ranged from 5 to 15 mm/s. Fine fluttering motion of the normal open aortic cusps was often observed during systole. Fluttering of normal open mitral valve cusps during diastole was usually observed with aortic regurgitation or atrial fibrillation and flutter. Fluttering of the aortic, mitral, or tricuspid cusps in the closed or coapted position was never observed in a normally functioning valve. The echocardiographic features of the cusps are similar in both Hancock and Carpentier-Edwards valves. However, they can be differentiated from each other by 2-D study by their stent shape and configuration.

The average echocardiographically measured thickness of the porcine bioprosthetic valve in the closed position when implanted in a mitral position was 1.23 ± 0.12 mm for the mitral and 0.91 ± 0.07 mm for the aortic position. Valve thickness remained the same or increased only minimally during serial follow-up study except for 14 valves that became ≥3 mm thick.[23] In this latter group we observed a significant increase in the occurrence of valve dysfunction.[23] Progression of valve thickness is shown in Figure 2 in a patient with serial follow-up study.

Abnormal function: Fifty-nine instances of valvular dysfunction occurred (Table I); 39 were ascribed to spontaneous cusp degeneration, 12 to infective endocarditis, 5 to associated paravalvular regurgitation, and 1 each to regurgitation of redundant aortic cusps, mitral valve thrombus, and supravalvular aortic stenosis due to inward bending of the stents. Diagnostic echocardiographic abnormalities were observed in 69% of the patients. Valvular pathology was established within 1

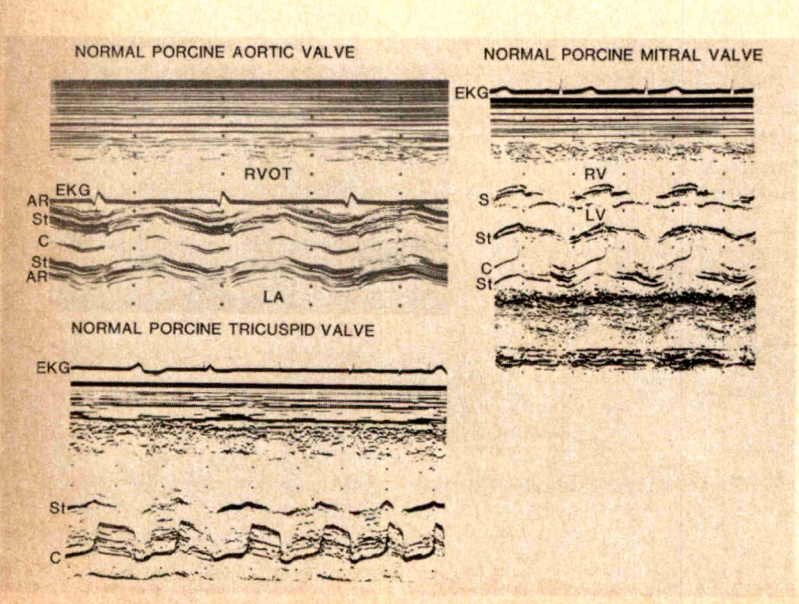

FIGURE 1. M-mode echocardiogram of a normal aortic, tricuspid, and mitral porcine bioprosthetic aortic valve. All valves are enlarged to demonstrate the cusps (C) which are thin. AR = aortic root; C = cusps; EKG = electrocardiogram; LA = left atrium; LV = left ventricle; RV = right ventricle; S = ventricular septum; St = stents; RVOT = right ventricular outflow tract.

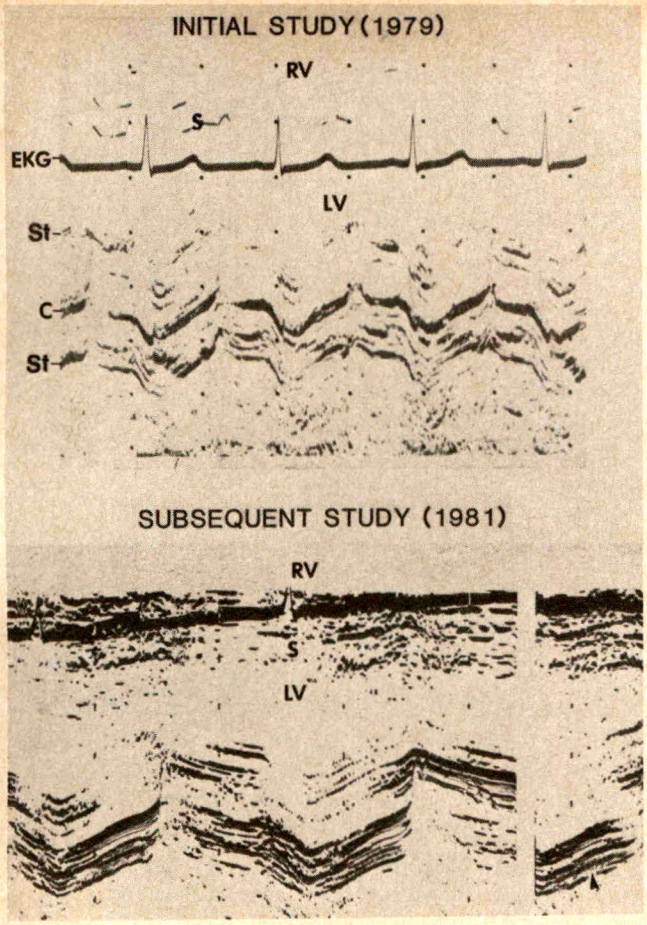

FIGURE 2. M-mode echocardiogram of porcine bioprosthetic mitral valve (magnified view). **Upper panel,** 1979; **lower panel,** 1981, at time of clinical dysfunction. Note progressive increase in cusp thickening and subtle high-frequency systolic fluttering (**arrow head**). Abbreviations are as in Figure 1.

month by cardiac catheterization (38 valves) and/or open heart surgery or autopsy (45 valves).

Spontaneous cusp degeneration: Spontaneous degeneration of the bioprosthesis occurred in 39 patients, 34 of whom had severe valve regurgitation and 5 had stenosis. Valve regurgitation is usually associated with a tear or perforation of a thickened and calcified cusp. Perforation and valve tears may also occur in valves that appeared to be of normal thickness on gross inspection. However, stenosis was always the result of thickening or calcification of the cusps, or both.

Of 34 patients with severe valve regurgitation, 28 developed rapidly progressive exertional dyspnea and 6 were minimally symptomatic and had detection by routine echocardiography. Two patients with stenotic aortic valves developed symptoms of angina, dyspnea, and near-syncope. All 3 patients with stenotic mitral valves had symptoms of progressive dyspnea.

The characteristics of echocardiographic abnormalities in spontaneous valve degeneration depend on whether the valves are predominantly stenotic or regurgitant. Echocardiographic valve abnormalities were observed in 85% of clinically significant dysfunctioning porcine bioprosthetic valves (Table II). All 5 stenotic valves produced abnormal echocardiograms, whereas valve regurgitation occurred with normal cusp echoes in 6 of 34 instances (18%).

Cusp degeneration causing regurgitation: Valve regurgitation was echocardiographically characterized by cusp fluttering, flail cusp motion, and increased cusp thickness. Cusp fluttering in the closed position of both aortic and mitral valves was distinctly abnormal. Diastolic fluttering of the aortic valve and systolic fluttering of the mitral valve in M-mode studies was diagnostic of porcine bioprosthetic valve regurgitation (Fig. 3 and 4). The findings were observed in 28 of 34 (82%) regurgitant valves with similar frequency in both the mitral and the aortic position. On inspection, these regurgitant valves had tears in 1 or more cusps. Because normal valves did not exhibit flutter in the closed position, this finding was 100% specific and of predictive value for regurgitant valves.

Diastolic fluttering of the open mitral and tricuspid valves can be normal. However, it was the only abnormality observed in 2 regurgitant mitral and 2 tricuspid valves. In 5 other regurgitant mitral valves, both diastolic and systolic fluttering were observed. When the valve cusps were poorly supported, flail motion and hyperflexion of parts of the disrupted aortic porcine valve cusps could be seen in the left ventricular outflow tract in diastole (Fig. 3). Portions of the flail mitral valve cusps were similarly observed in the left atrium during systole or left ventricular outflow tract during diastole (Fig. 4). This flail valve motion was particularly well appreciated in the 2-D mode study when the cusps were also thickened.

Echocardiographic cusp thickness of ≥3 mm was observed in 24 of 34 (70%) regurgitant valves. All such valves exhibited some localized or generalized cusp thickening or calcification on gross examination. In 6 valves with clinical evidence of significant valvular regurgitation, echocardiography was normal in 3 valves in the aortic position and 3 in the mitral. As increased valve thickness was also observed with 14 normal functioning valves, the predictive valve of this echocardiographic finding for regurgitant valves was only 63%.

Cusp degeneration causing stenosis: In 5 stenotic porcine valves, measurements of the valve thickness were always ≥3 mm. Aortic valves (Fig. 5) in 2 patients manifested reduced systolic cusp opening of 3 and 6 mm

TABLE II Clinical and Echocardiographic Characteristics of Spontaneous Valvular Degeneration

	Patients With Clinical Syndrome (n)	Echocardiographic Valve Abnormality	
		n	%
Valvular regurgitation			
Mitral	21	18	86
Aortic	11	8	73
Tricuspid	2	2	100
Valvular stenosis			
Mitral	3	3	100
Aortic	2	2	100
Total	39	33	85

Note the thickened and flail cusps (C) in the left ventricular outflow tract. AV = aortic valve; MV = mitral valve; other abbreviations are as in Figure 1 in this and subsequent figures.

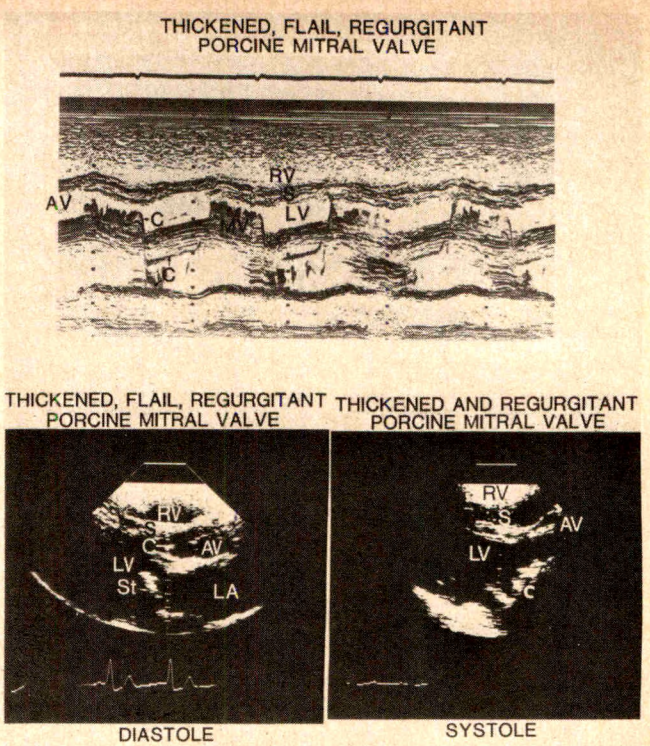

FIGURE 4. M-mode and 2-dimensional (2-D) echocardiogram of a thickened regurgitant and flail porcine bioprosthetic mitral valve (MV). **Upper panel,** note thickened cusps (C) with coarse diastolic and coarse and fine systolic fluttering (**arrows**). **Lower panel,** 2-D parasternal long-axis view during diastole and systole. Note the thickened cusp (C), which, during diastole, bends and hyperflexes anteriorly and toward the aortic valve (AV).

(normal 10 to 24). Although dense cusp echoes were demonstrated in all 3 stenotic mitral valves, the presence of reduced (<5 mm/s) initial diastolic stent slope motion was observed in only 1 instance.[9]

Infective endocarditis: The 12 patients with infective endocarditis presented with high fever, new murmurs, and positive blood cultures. Cusp echoes of ≥3 mm and a suggestion of valvular vegetations (Fig. 6) were observed in 4 of 12 patients by M-mode study and in 3 of the 6 studied by 2-D echocardiography. In 2 patients, no vegetations were seen despite their presence at surgery or autopsy.

Paravalvular regurgitation: Of 5 patients with this hemodynamic abnormality, 4 had normal studies. The only patient with an abnormal echocardiogram had a subanular aneurysm with marked displacement of the entire prosthesis into the left atrium (Fig. 7).

Mitral valve thrombus: One patient with apparent mitral valve thrombus was observed to have a marked, transient increase in cusp echoes (Fig. 8). This patient complained of shortness of breath and exhibited a diastolic murmur. These features, as well as increased cusp echoes, resolved after 1 week of intravenous heparin therapy. Although we cannot be absolutely certain, the clinical course and echocardiographic findings are highly suggestive of a thrombus on the porcine bioprosthetic valve.

Aortic insufficiency due to cusp redundancy: Occasionally the porcine bioprosthetic valve may not be structurally normal at the time of replacement. In 1 such patient, severe aortic regurgitation developed soon after aortic valve replacement. This patient had chaotic diastolic cusp fluttering. At surgery, the valve was intact, free of vegetations, and without a paravalvular leak. However, 1 aortic cusp was extremely redundant and poorly supported by the stent.

Supravalvular aortic stenosis due to inward bending of the stent: One patient had obstruction in the supravalvular area causing a loud systolic murmur, severe hemolytic anemia, and hemodynamic evidence of outflow obstruction.[10] M-mode study of this valve revealed normal cusps with a reduced internal diameter of the stent measuring 10 mm (normal >15 mm). Presence of marked inward bending of the stent with otherwise normal cusps was found at surgery.

Discussion

Normal functioning porcine bioprosthetic valves (Hancock or Carpentier-Edwards) have thin cusps and exhibit normal closing and opening during the cardiac

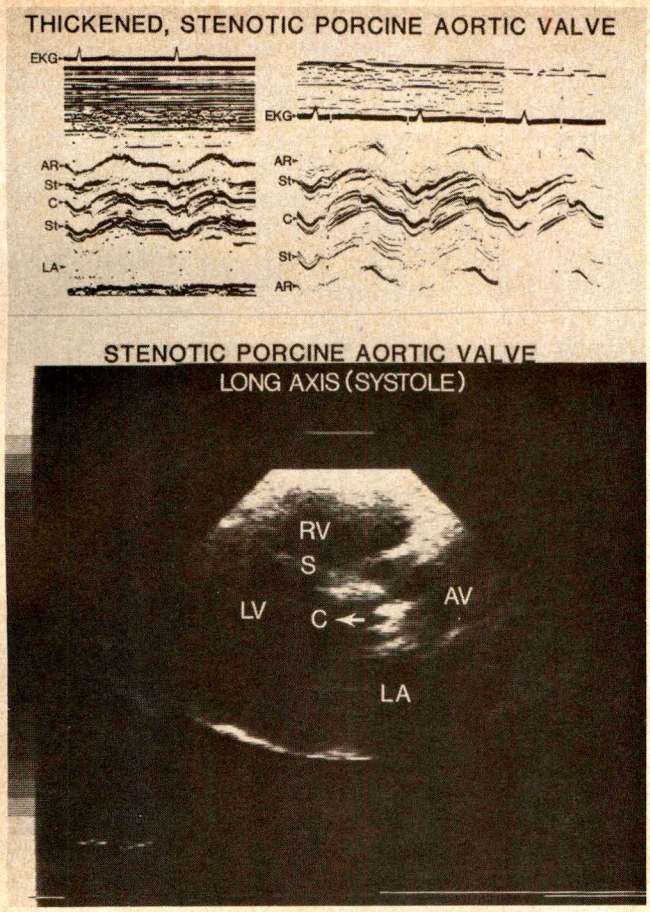

FIGURE 5. M-mode (**upper panel,** normal and magnified views) and 2-dimensional parasternal long-axis view (**lower panel**) echocardiogram of a thickened and stenotic porcine bioprosthetic aortic valve. Note the thickened cusp (C) with reduced systolic opening.

cycle. The gross pathology of degenerated porcine prosthetic valves usually reveals thickened and calcified cusps, with or without tears of the cusps.[24–26] However, tears of the cusps may occur without thickening or calcification. The presence of echocardiographic cusp fluttering of the closed valve indicates torn, nonsupported cusp tissue as a result of vibrations created at the margins of the tear. Similar fluttering has been observed with flail native valves and regurgitation associated with aortic homograft valves.[9,27] In our experience, fluttering of the mitral and aortic porcine valve in the closed position is always indicative and highly specific of regurgitation. On occasion, significant regurgitation may occur in the absence of demonstrable fluttering. It is usually associated with small valve tears, and the narrow ultrasonic beam may have missed the involved valve segment. Enlarging and slow scanning of the entire valve circumference while recording at fast paper speed will reduce the likelihood of missing this subtle finding. Fluttering of the mitral and tricuspid valves, when open in diastole, can be observed in both regurgitant and normal valves. In the normal functioning mitral valve, diastolic fluttering was observed particularly in the presence of aortic regurgitation and atrial fibrillation

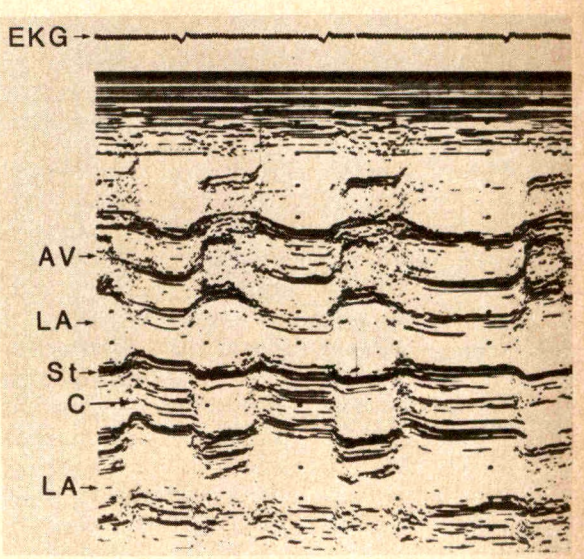

FIGURE 7. M-mode echocardiogram of a mitral porcine bioprosthetic valve with severe perivalvular regurgitation and displacement of both stent and cusp echoes in the left atrium.

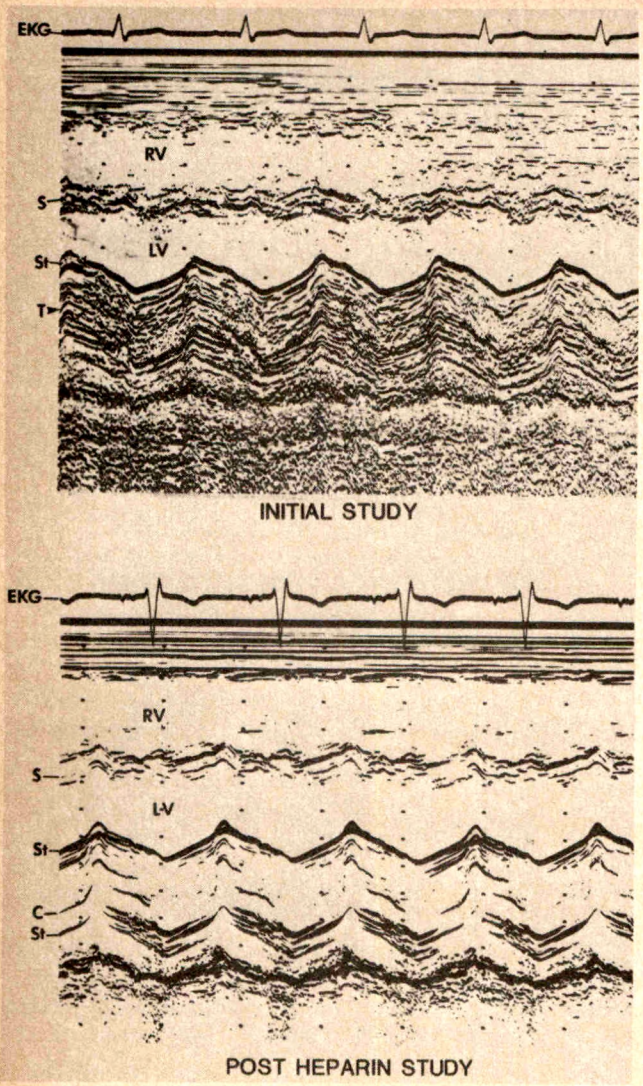

FIGURE 8. Upper panel, M-mode echocardiogram of a probable thrombus on porcine bioprosthetic mitral valve. Note the dense echoes of the thrombus (T) in the region of the mitral valve. **Lower panel,** same valve after probable thrombolysis. Note normal cusp (C) echoes.

and has been reported with paravalvular regurgitation.[18]

Cusp thickening is a sensitive and early indication of valve degeneration. Our experience indicates that cusp thickness ≥3 mm in asymptomatic patients usually represents subclinical valve degeneration and frequently leads to clinical signs of valve dysfunction.[23] Because symptoms of valve dysfunction may take many months to develop, we do not advise replacement of thickened valves until the patient becomes symptomatic. However, cusp thickening of ≥3 mm is not highly specific for spontaneous valve degeneration, because some thickening can be observed with valve vegetations or thrombus. It may also be an artifact created by a very high gain setting.

The echocardiographic characteristics of stenotic aortic porcine prosthetic valves are similar to those of native aortic valve stenosis. In porcine bioprosthetic mitral valves, the echocardiographic findings were similar to those reported by Horowitz et al[9] for stenotic mitral homograft valves except that reduced initial diastolic stent slope was present in only 1 of the 3 patients. Furthermore, a reduced diastolic stent slope (<5 mm/s) was also observed with normally functioning mitral valve prostheses when left ventricular compliance was decreased. As all stenotic valves have echocardiographic cusp thickness ≥3 mm, it has been our practice to measure transvalvular pressure gradients in any patient who develops dyspnea in association with echocardiographic evidence of increased valve thickness.

In the evaluation of porcine bioprosthetic valve endocarditis, both M-mode and 2-D echocardiography were neither sensitive nor specific. Shaggy, fluttering echoes characteristic of native valve vegetations[28] were observed in only 1 patient. Similar shaggy echoes were also observed in patients who had primary valve degeneration and regurgitant valves. Schapira et al[17] reported the superiority of 2-D over M-mode echocardiography in the evaluation of porcine bioprosthetic valve vegetations and masses, but we could not support this opinion.

Because severe paravalvular regurgitation is usually due to technical factors at the valve ring and not to cusp abnormalities, it is not surprising that the valve echoes of all but 1 patient with this entity were normal. Echocardiographic features of paravalvular mitral regurgitation, previously reported, increased initial diastolic slope of the anterior stent (>33 mm/s) and systolic excursion of the anterior cusps (>10 mm), and fine diastolic fluttering of the cusps[14,18] was not observed in any of our patients.

Increased cusp echoes in our patient with probable mitral valve thrombus was similar to those reported by Bloch et al.[14] Reduced diastolic excursion of the leaflet as reported by Horowitz et al[9] could not be appreciated in our patient because of echoes from the overlying thrombus. Chandraratna and San Pedro[15] reported an increase in the thickness of the posterior stent and a reduction of the space between the stent and the aortic root to be diagnostic of an aortic porcine bioprosthetic valve thrombus. We have observed this finding with normally functioning valves.

Structural abnormalities of the valve occur, albeit rarely. Our 1 patient with a redundant aortic cusp had diastolic fluttering echoes similar to those reported with regurgitant native myxomatous aortic valves.[29] Valvular aortic stenosis due to inward bending of the stent should be considered in any patient with an echocardiographically determined internal aortic stent diameter <15 mm.

We did not find that either 2-D or M-mode echocardiography provided a unique advantage. Valve fluttering is better identified in the M-mode and flail valve motion by 2-D studies. Each technique was important and provided a different visualtion modality. Bioprosthetic valve dysfunction is thus best identified using both techniques.

The echocardiogram can provide critical information regarding the function of porcine bioprosthetic valves and can substantially assist in the decision to replace

these valves in a symptomatic patient. Because patients with valvular heart disease often have periods of cardiac decompensation unrelated to valve dysfunction, careful echocardiographic evaluation may prevent unnecessary valve replacement in functionally normal valves and expedite surgery in those patients with significantly dysfunctioning valves.

Abnormal Cardiovascular Regulation in the Mitral Valve Prolapse Syndrome

F. ANDREW GAFFNEY, MD, BRUCE C. BASTIAN, MD, LYNDA B. LANE, RN, W. FRED TAYLOR, MS, JURETA HORTON, PhD, JAMES E. SCHUTTE, PhD, ROBERT M. GRAHAM, MD, WILLIAM PETTINGER, MD, and C. GUNNAR BLOMQVIST, MD,
With the technical assistance of WILLIE E. MOORE, Jr.

Studies of patients with mitral valve prolapse syndrome have suggested autonomic nervous system dysfunction, but a precise definition of mechanisms is lacking. We measured supine and standing heart rate, blood pressure, cardiac output, oxygen consumption, plasma catecholamines, and blood volume in 23 symptomatic women with both echocardiographic and phonographic signs of MVP and in 17 normal control subjects. An analysis of the results revealed 2 distinct subgroups of patients: those with normal heart rates but increased vasoconstriction (Group I, n = 10) and those with orthostatic tachycardia (Group II, n = 13). Group II patients had heart rates at rest supine of 97 ± 3 compared with 79 ± 2 in Group I patients and 78 ± 8 in control subjects. Estimated total blood volumes were lowest in Group I patients, intermediate in Group II patients, and highest in control subjects ($p < 0.05$). Other measurements at rest supine were similar in patients and controls. After standing for 5 minutes, patients had a higher mean plasma epinephrine value, diastolic blood pressure (81 ± 2 versus 74 ± 3 mm Hg, $p < 0.05$), and peripheral resistance (1,878 ± 114 versus 1,414 ± 92, dynes s cm^{-5}, $p < 0.01$), wider arteriovenous oxygen difference (6.7 ± 0.4 versus 5.3 ± 0.5 vol%), and lower stroke volume index (26 ± 2 versus 33 ± 2 ml/m^2, $p < 0.01$) than did the control subjects. Cardiac output was normal in Group II patients but reduced in Group I patients, who demonstrated marked vasoconstriction. No patient had evidence of a "hyperkinetic" circulatory state. A cycle of decreased forward stroke volume, vasoconstriction, and blood volume contraction appears to be present in at least some symptomatic patients with MVP.

Reports from our laboratory[1,2] and others[3–5] have documented the presence of autonomic nervous system dysfunction in some patients with the mitral valve prolapse (MVP) syndrome, but a precise definition of the regulatory abnormalities has not been presented. Coghlan et al[3] reported that some patients appeared to have excessive vagal tone and responsiveness. Boudoulas et al[5] recently suggested that patients with MVP are hyperadrenergic, with increased beta-adrenergic tone and responsiveness. Our previous work provided no evidence for increased beta-adrenergic activity, but rather, suggested that alpha-adrenergic hyperactivity was present. A common feature in all of these reports is that the conclusions were based partly on the response to orthostatic stress produced by head-up tilt,[3] standing,[4,5] or lower body negative pressure.[1] Because of differences in findings, we carried out a second set of studies in which the hemodynamic and neuroendocrine responses of patients with MVP to orthostatic stress were analyzed.

Methods

Patients: The patient group consisted of 23 women aged 36 ± 2 years (mean age ± standard error) (range 21 to 60). Patient characteristics are shown in Table I. All patients had presented for medical care because of symptoms commonly associated with MVP such as chest pain, palpitations, easy fatigability, and near-syncope, often in response to orthostatic

stress. None had clinical evidence of significant mitral regurgitation, coronary artery disease, hypertension, diabetes mellitus, or alcoholism. None of the subjects in this study group met Diagnostic Standards Manual-III criteria for panic disorder. Neuroactive medications were discontinued at least 1 week before study. MVP was diagnosed by 2-dimensional (2-D) echocardiography and phonocardiography.[1] Criteria for echocardiographic diagnosis included prolapse of 1 or both leaflets behind an imaginary line through the mitral anulus in either the apical 4-chamber or the parasternal long-axis views. All subjects had persistent auscultatory findings including isolated single or multiple nonejection clicks with or without the murmur of mitral regurgitation. No subject with "silent" or "echo-only" MVP was included. Family studies in more than half the subjects confirmed the familial nature of the disorder.

Control subjects for the hemodynamic studies were 17 women, mean age 27 ± 1 years. All were healthy nonsmokers, taking no cardio- or neuroactive medications. They were employees of the University of Texas Health Science Center or the Parkland Memorial Hospital in Dallas, Texas. Most were sedentary and none participated regularly in athletics.

Procedures: Heart rate was measured by the electrocardiogram and displayed digitally on a beat-to-beat basis (Quinton Cardiotachometer, model 511). Indirect arterial blood pressure was measured semiautomatically with a device that records simultaneous cuff pressure and Korotkov sounds (Narco Bio-Systems Electro-Sphygmomanometer, PE-300). Cardiac output was measured with an acetylene rebreathing technique previously validated in our laboratory. The coefficient of variation when compared with simultaneous indocyanine green cardiac outputs was 4.3% over a range of 4 to 19 liters/min.[6] Oxygen consumption and cardiac output were simultaneously measured to calculate arteriovenous oxygen differences. Plasma catecholamines were measured by a radioenzymatic technique.[7] Plasma volume was measured by standard dilution techniques using either human serum albumin tagged with iodine-125 (RISA) or Evans blue dye.[8,9] Iodine-125 was used in 4 of 23 patients and 3 of 17 control subjects. Measurement of plasma volume by both RISA and Evans blue methods in 7 subjects revealed a nonsignificant mean difference of 183 ± 104 ml (RISA values being higher). Total blood volume was estimated from measurement of plasma volume and peripheral venous hematocrit corrected for trapped plasma and the difference between central and peripheral venous hematocrit.[10,11]

Protocol: The study was approved by the local Human Research Review Committee. Each subject gave informed written consent before study. Although most patients and subjects had participated in similar hemodynamic studies previously, care was taken to familiarize each person with the laboratory procedures and equipment. This familiarization was always accomplished a day before the study was performed. Testing of patients and control subjects was performed concurrently.

On the first day of study, a small needle was placed in an arm vein and kept open with heparinized saline solution. Baseline cardiac output, heart rate, and blood pressure were measured. After at least 20 minutes of supine rest, a venous blood sample was drawn for plasma catecholamine determination. Hemodynamic measurements were then repeated. The subject then stood quietly for 5 minutes, after which catecholamine sampling and hemodynamic measurements were again repeated.

Measurement of plasma volume was performed on a second day with the subject at rest supine for approximately 1 hour. Hematocrit was determined on simultaneously obtained peripheral blood samples.

TABLE I Subject Characteristics

	Mitral Valve Prolapse		Normal Control Subjects
	Group I (HR <100)	Group II (HR ≥100)	
n	10	13	17
Age (yr)*	39.0 ± 4.1	33.5 ± 2.4	26.9 ± 1.0
Height (cm)	167.7 ± 2.0	167.6 ± 2.2	167.8 ± 1.8
Weight (kg)	56.8 ± 2.3	55.7 ± 2.6	58.8 ± 1.6

* $p < 0.01$.
BSA = body surface area; HR = heart rate.

Statistical analysis was performed with the use of the Statistical Analysis Systems programs.[12] Because an initial analysis of the results revealed the presence of 2 hemodynamically distinct subsets of patients, an analysis of variance was used to test for differences between the control subjects, the patients with normal supine and standing heart rates (Group I), and those with tachycardia when standing (Group II). Results are expressed as the mean ± standard error of the mean. Differences were statistically significant to a level of probability of $p < 0.05$.

Results

Supine: Cardiac and stroke volume indexes, calculated arteriovenous oxygen differences, and total peripheral resistance for patients and control subjects were not significantly different (Fig. 1). Mean arterial pressure was higher in the patients. Heart rate was increased only in the patients with standing tachycardia (Group II). Mean plasma norepinephrine levels were similar, but plasma epinephrine levels were significantly higher in patients compared with the control subjects (31 ± 5.7 versus 11 ± 3.7 pg/ml, $p < 0.01$). These values, although at the lower limits of detectability, correlated significantly with heart rate ($p < 0.001$) and systolic blood pressure ($p < 0.001$).

Standing: As expected, cardiac indexes decreased significantly on standing in both patients and control subjects; Group I patients had lower mean cardiac indexes than did Group II patients or control subjects. Both patient groups had a higher mean diastolic arterial blood pressure (81 ± 3, 79 ± 2, and 72 ± 2 mm Hg, $p < 0.05$, respectively), with a subnormal stroke volume index ($p < 0.05$). Plasma norepinephrine levels increased in all groups. Again, the intergroup differences were not statistically significant, but several individual patients had very large increases on standing, and there was a downward progression from Group II patients with tachycardia to normal control subjects (Fig. 2). Plasma epinephrine levels were not significantly different from values obtained in the supine position. Measurements of heart rate, blood pressure, and stroke volume also showed large interindividual differences among the patients. Total peripheral resistance (Fig. 1) was significantly higher in Group I patients, with no tachycardia; Group II patients had intermediate values, whereas the controls had the lowest. An identical pattern was seen for calculated arteriovenous oxygen difference (6.90 ± 0.60, 6.77 ± 0.39, and 5.70 ± 0.26 vol%, respectively).

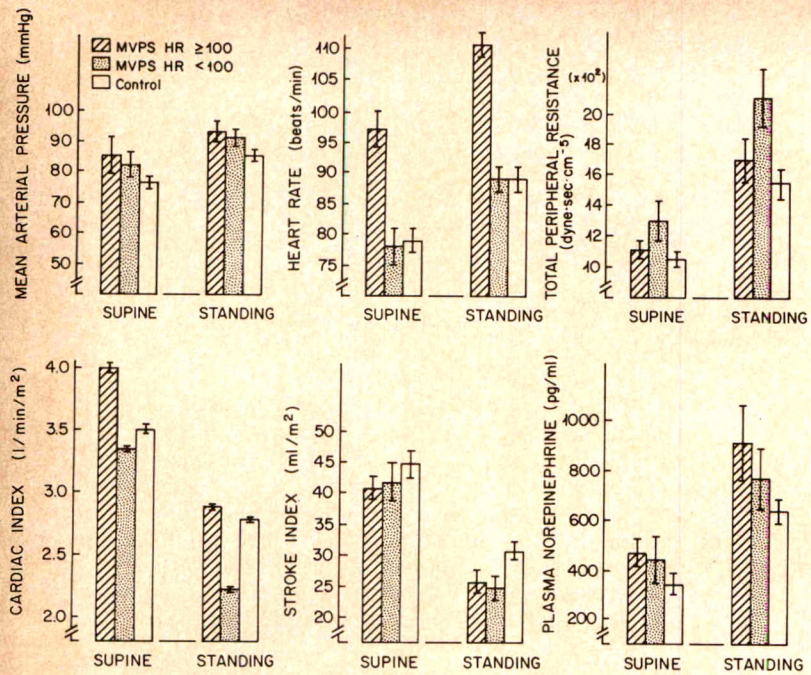

FIGURE 1. Hemodynamic and neuroendocrine measurements in patients with normal heart rates (Group I), patients with orthostatic tachycardia (Group II), and normal control subjects. MVPS = mitral valve prolapse syndrome; HR = heart rate. Values are mean ± 1 standard error.

Plasma volume: Overall, patients had a significantly higher hematocrit (40.3 ± 0.9 versus 37.6 ± 0.6%, $p < 0.02$) and lower plasma volume, both in absolute terms (2,836 ± 82 versus 3,222 ± 123 ml, $p < 0.01$) and when corrected for height (17.0 ± 0.5 versus 19.2 ± 0.7 ml/cm, $p < 0.01$). There were similar differences in absolute blood volume and when correction was made for height or body surface area.[13] Group I patients, who had the highest total peripheral resistance, had the lowest blood volumes, 4,012 ± 100 ml; Group II patients had intermediate values, 4,406 ± 133 ml, and control subjects had 4,798 ± 231 ml ($p < 0.05$).

Discussion

The present study demonstrates that a subgroup of patients with MVP, characterized by the presence of symptoms and both echocardiographic and auscultatory/phonographic signs of prolapse, have an abnormal response to orthostatic stress. They develop excessive vasoconstriction and, in some cases, tachycardia, and maintain a higher mean arterial blood pressure (standing) than do normal control subjects. By themselves, heart rate and blood pressure data suggest a hyperkinetic response, but when examined relative to the overall hemodynamic response, a different pattern emerges. Stroke volume tends to be slightly lower in the supine position, and on standing is significantly lower in both groups of patients with MVP. In Group II patients, there is tachycardia on standing, and cardiac output is maintained at normal levels. In Group I patients, the response is actually hypokinetic, as reflected in the tendency toward wider calculated arteriovenous oxygen differences in the patient group in the upright position. Group I patients, when standing, seem to compensate for decreased forward stroke volume by vasoconstriction. However, if the patients had a purely compensatory response, their blood pressure should have been slightly lower than normal, rather than significantly higher than the control group values.

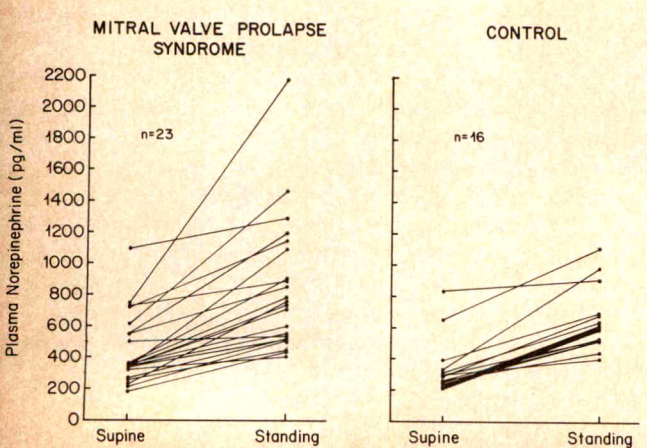

FIGURE 2. Supine and standing plasma norepinephrine values for each patient and each normal control subject.

The hemodynamic heterogeneity of the patients makes interpretation of the average norepinephrine responses difficult. Other investigators have found small but significant differences between patients with MVP and control subjects.[4,5] Our patients also tended to have higher plasma norepinephrine levels, but interindividual variations were large and the intergroup differences did not reach statistical significance (Fig. 2). Whether or not a group difference will be recorded is determined in large part by the number of patients in the study who have orthostatic intolerance and tachycardia as major complaints. The finding that certain patients with MVP have tachycardia and increased norepinephrine levels on standing does not constitute proof of beta-adrenergic hyperactivity, that is, an ab-

normal hemodynamic state primarily attributable to abnormal levels of beta-adrenergic stimulation. Patients with the higher norepinephrine levels also had the higher heart rates which served to maintain cardiac output to a more normal degree than did the "normal" heart rate. The 13 patients with the highest norepinephrine levels and standing heart rates over 100 beats/min (Group II patients) had a mean cardiac index of 2.9 ± 0.2 liters/min/m^2, whereas the patients (Group I) with standing heart rates under 100 had a significantly lower cardiac index (2.3 ± 0.2 liters/min/m^2). Other investigators[4,5] noted an apparently inappropriate response in patients with MVP on standing, but cardiac output measurements were not performed. The lack of cardiac output data led to the conclusion that a hyperkinetic state was present, whereas the present study suggests that the heart rate response is reasonably appropriate considering the stimulus, that is, an orthostatic blood volume shift producing a low forward stroke volume. The increase in arterial pressure above normal levels during orthostatic stress despite a substantial decrease in cardiac output has been noted previously[1] and suggests an abnormal alpha-adrenergic responsiveness with appropriate beta-adrenergic activity. The alpha-adrenergic hyperactivity in the upright position may eventually lead to a chronic state of vasoconstriction and increased plasma catecholamine levels. The fact that orthostatic intolerance in some patients with pheochromocytoma provides some support for the hypothesis that a neuroendocrine postural response that is beneficial on a short-term basis may contribute to a chronic state of orthostatic intolerance.[14] Similar changes may also be seen in subjects rendered hypovolemic by prolonged bed rest or space travel.[15]

A possible link between excessive vasoconstriction, hypovolemia, and MVP is presented in Figure 3. A large postural reduction in forward stroke volume leads to marked vasoconstriction and increased catecholamine release. This chronic vasoconstriction leads to hypovolemia, which produces an even greater reduction in forward stroke volume in the presence of MVP. A vicious cycle is established. Substantial mitral regurgitation is not a prerequisite. The increasing volume contained by the ballooning leaflets with decreasing ventricular size may produce, for any given reduction in left ventricular filling pressure, an exaggerated decrease in resting fiber length, fiber shortening, and forward stroke volume. Our preliminary finding of a marked reduction in left ventricular end-diastolic volume in patients with MVP with upright rest or exercise supports the concept that decreased ventricular filling in the upright position is a prominent feature in the pathophysiologic mechanisms of this syndrome.[2] Semiquantitative measurement of leg volume changes during orthostatic stress produced by lower body negative pressure showed that patients with MVP did not have excessive blood pooling in their legs,[1] suggesting that the decrease in total blood volume is an important component of orthostatic intolerance in patients with MVP.

Such a decrease in blood volume might also be at least a partial explanation for the recent findings of Devereux et al,[16] who noted significantly lower sitting blood

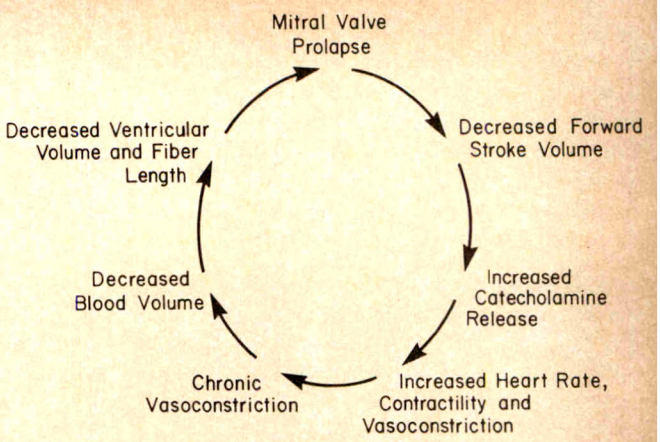

FIGURE 3. A proposed pathophysiology of orthostatic intolerance in symptomatic patients with mitral valve prolapse (MVP). A large myxomatous mitral valve would clearly have a facilitative role, but it is not necessary in order to have MVP or MVP symptoms related to orthostatic intolerance.

pressure in a large number of patients with MVP. The presence of an increased frequency of palpitations in Devereux's MVP patients[17] as well as ours[1] may reflect the presence of orthostatic intolerance as recently reported by Santos et al.[18] Such patients are commonly seen and, in addition to palpitations, give a history of near-syncope or syncope, but an ambulatory electrocardiographic recording often shows only sinus tachycardia. Unless a diary of patient activity is available, the extent of tachycardia without exertion or excitement is often not appreciated.

The existence of parasympathetic and alpha-adrenergic dysfunction in some patients with MVP suggests a primary abnormality affecting the autonomic nervous system. Two-dimensional echocardiographic studies in our patients, who all had auscultatory signs of prolapse, revealed a wide spectrum of mitral leaflet size and degree of valvular prolapse. These factors appear to be unrelated to the degree of symptoms present. Jeresaty[19] noted a similar lack of correlation between symptoms and the degree of prolapse, which suggests that at most, the prolapsing valve plays a facilitating role in producing these orthostatic symptoms, but that it is not their primary cause. This subgroup of patients with orthostatic intolerance clearly has a syndrome consisting of distinctive anthropometric characteristics,[20] autonomic dysfunction,[1–5] and myxomatous degeneration of the mitral valve. Whether MVP is causally related to the symptoms of the patients in the present study is not known. Additionally, the presence of chronic vasoconstriction, hypovolemia, and orthostatic and exercise intolerance in similar patients without MVP (personal observation) suggests that the pathophysiologic mechanisms are by no means specific to MVP, but rather, explain the symptoms found in a variety of cardiac disorders. Data from other investigators provide some support for the hypothesis that there are other subgroups of patients with anatomically normal mitral valves, but with symptoms and signs of the MVP syndrome because of autonomic dysfunction including an increased inotropic state with reduced left ventric-

ular volume. Wooley[21] reported the clinical similarities between patients with MVP and hyperkinetic syndromes, such as the vasoregulatory asthenia described by Holmgren et al[22] and the hyperkinetic heart syndrome reported by Gorlin.[23] Whether some of these patients classified as hyperkinetic actually have midsystolic clicks, murmurs, and echocardiographic evidence of MVP is not known.

Noncardiovascular Findings Associated With Heart Disease in the Idiopathic Hypereosinophilic Syndrome

JOHN B. HARLEY, MD, PhD, ANTHONY S. FAUCI, MD, and HARVEY R. GRALNICK, MD

Heart disease characterized by endomyocardial fibrosis is one of the major causes of morbidity and mortality in the idiopathic hypereosinophilic syndrome. From our series of 50 patients with idiopathic hypereosinophilia, we defined the noncardiovascular characteristics that distinguish patients at risk of developing endomyocardial fibrosis from those who remain free of heart disease. These groups did not differ with respect to the extent of eosinophilia or the duration of disease. Patients with clinically overt heart disease were more likely ($p < 0.05$) to be male and HLA-Bw44 positive and have splenomegaly, thrombocytopenia, elevated serum levels of vitamin B_{12}, and hypogranular or vacuolated eosinophils and abnormal early myeloid precursors in the peripheral blood. These idiopathic hypereosinophilic patients with heart disease were also more likely to have fibrosis and decreased megakaryocytes in the bone marrow. In contrast, those who remained free of heart disease tended to be female and have angioedema, hypergammaglobulinemia, elevated serum levels of immunoglobulin E (IgE), and circulating immune complexes.

Therefore, in the idiopathic hypereosinophilic syndrome, male patients with a myeloproliferative type disorder and the HLA-Bw44 haplotype were at a much increased risk for the development of endomyocardial fibrosis. However, those patients with a hypersensitivity-like illness and angioedema who were female did not develop heart disease. Appreciation of this relative degree of risk for the major complication of the idiopathic hypereosinophilic syndrome should prove useful in the early identification and appropriate treatment of patients in whom endomyocardial fibrosis might develop.

The endocardial disease associated with idiopathic eosinophilia was first appreciated by Löffler[1] in 1936. Since then, numerous reports and small series of patients have firmly established the association of these findings.[2–6] Indeed, cardiovascular disease has been recognized as the major cause of morbidity and mortality in patients with idiopathic eosinophilia.[6–8] The pathophysiologic mechanism that relates endomyocardial fibrosis to idiopathic hypereosinophilia is not known, although some patients with idiopathic hypereosinophilia and heart disease have morphologic changes in their peripheral blood eosinophils.[9]

In our experience not all patients with idiopathic hypereosinophilia develop clinical heart disease. This study was performed to discover the noncardiovascular findings that may distinguish the patients who develop heart disease from those who remain free of cardiovascular complications.

Methods

Patients: The 50 patients included in this study were admitted to the National Institutes of Health Clinical Center under a National Institutes of Allergy and Infectious Diseases protocol. Patients were followed 2 to 14 years, although some have had eosinophilia for >20 years. Only those patients who satisfied the diagnostic criteria for the idiopathic hypereosinophilic syndrome were included in the study.[6] These criteria include (1) unexplained eosinophilia ≥6 months, (2) organ system involvement (any organ system except the skin alone is acceptable), and (3) the inability to establish an alternative diagnosis despite exhaustive evaluation.

The first available peripheral smears and bone marrows from each patient were read and scored blindly according to previously described criteria.[10] In addition, criteria were established to assess eosinophil morphologic characteristics. Eosinophils were scored as hypogranular if <50% of the area of the cellular cytoplasm on smear contained granules. Likewise, eosinophils that contained 10 or more vacuoles were scored as vacuolated.

Studies of eosinophil morphology showed that the determination of vacuolation and hypogranularity was not changed by storage at room temperature for up to 6 hours, by blood collection by vacutainer (EDTA), fingerstick or syringe, nor

TABLE I Patient Groups in the Idiopathic Hypereosinophilic Syndrome According to Cardiac Involvement: 50 Patients

	n	%	Total
Clinically overt cardiac involvement		42	21
Progressive valvular disease	16/21		
Deterioration of pump function	17/21		
Multiple emboli	8/21		
Subclinical cardiac involvement		12	
A. Increased septum or free wall thickness	4/6		
B. Increased density of the posterior mitral leaflet	3/6		
C. Ventricular filling defect	0		
Other cardiac disease		6	3
No evidence of cardiac disease		40	20

by using stained smears versus unstained smears evaluated by phase microscopy. Normal eosinophils did not become hypogranular or vacuolated, and the degree of hypogranularity and vacuolization of the abnormal eosinophils did not progress.

Classification of patients: Patients were assigned to 1 of 4 groups. Group I consisted of patients with overt cardiovascular disease as defined by the presence of either progressive valvular heart disease, congestive heart failure, or ≥3 embolic events to different arterial sites. Group II included patients with echocardiographic (M-mode or 2-dimensional) or electrocardiographic abnormalities consistent with idiopathic eosinophilia,[7–11] but without clinically overt heart disease. Group III included patients who had heart disease with a cause unrelated to idiopathic eosinophilia. Group IV patients had no heart disease.

Statistical analysis: The 2-tailed Student *t* test was applied to apparent differences in the anti-log of the log mean of quantitative determinations between groups. Fisher's exact test was used to compare the prevalence of characteristics between subpopulations. Survival data were compared by the Wilcoxon test. Differences were considered significant when the null hypothesis was rejected with >95% confidence.

Results

Of the 50 patients studied, 21 (42%) developed overt clinical heart disease (group I). Precordial murmurs that became louder were present in 16, mitral regurgitation

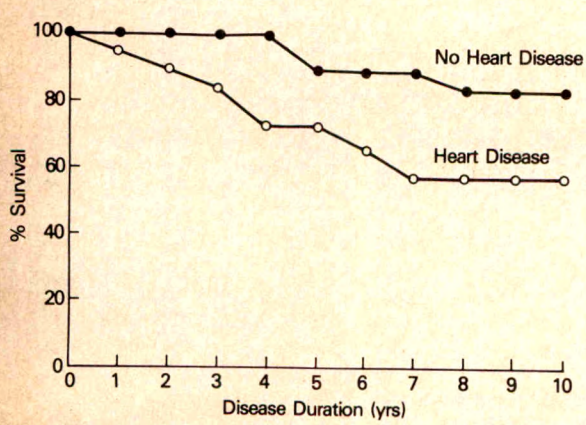

FIGURE 1. The survival of patients with overt heart disease (O) (group I) compared with that in patients who remain free of heart disease (●) (group IV).

TABLE II Comparison of Patient Groups

	Group I Heart Disease (n = 21)	Group IV No Heart Disease (n = 20)
Eosinophilia (cells/μl)*	20,700	19,000
Duration of disease (yr)	5.0	5.3
Average NIH follow-up (yr)	3.2	2.9
Average age at presentation (yr)	36	27

* Extent of eosinophilia at presentation.

in 15 of the 16. Otherwise, unexplained congestive heart failure occurred in 17 of these 21 patients and multiple emboli in 8 (Table I).

Six of the 50 patients had electrocardiographic or echocardiographic abnormalities in the absence of any evidence of overt clinical heart disease (group II). Four of these had left ventricular or free wall thickening on M-mode echocardiography, 3 had abnormal motion and thickening of the posterior mitral leaflet on 2-dimensional echocardiography, and 4 had nonspecific changes on electrocardiography (Table I).

Three patients had heart disease from other causes (group III). One had long-standing aortic regurgitation; 1 had a bicuspid and calcified aortic valve by echocardiography; and 1 had an acute myocardial infarction and angina pectoris. Groups II and III contained too few patients to yield meaningful results and, therefore, have been omitted from the following analysis.

Twenty patients had no evidence of heart disease (group IV). Direct comparison of the patients with heart disease (group I) with those patients who remained free of clinical heart disease (group IV) revealed no significant differences ($p > 0.1$) with respect to the extent of eosinophilia at presentation, the duration of disease from onset, the average follow-up at the National Institutes of Health, nor the average age at presentation (Table II). However, survival was longer in patients with no heart disease (Fig. 1).

Except for the finding of splenomegaly and for the 6 patients who had overt heart disease at presentation, initial examination was not helpful in discriminating patients at risk for the development of heart disease. Of the 21 patients with heart disease, 19 had splenomegaly at presentation or developed it during follow-up; only 5 of the 20 patients who remained free of heart disease had splenomegaly ($p \leq 0.005$). Of these 5 patients, 4 had an apparent underlying cause for an association with splenomegaly such as generalized lymphadenopathy (in 3 patients) and Budd-Chiari syndrome (1 patient).

Clinical laboratory studies revealed substantial differences between patient groups. Those patients who remained free of heart disease had elevated serum immune complexes, IgE, and Ig (IgG, IgM, or IgA) as shown in Table III. Only 2 of 15 group I patients had elevated immune complexes, 3 of 15 had elevated IgE, and only 1 of 15 had both. Group I patients were also more likely to have thrombocytopenia, elevated serum B_{12}, and HLA-Bw44 (Table IV). Other clinical laboratory studies, such as white blood cell count, degree of eosinophilia, abnormal leukocyte alkaline phosphatase,

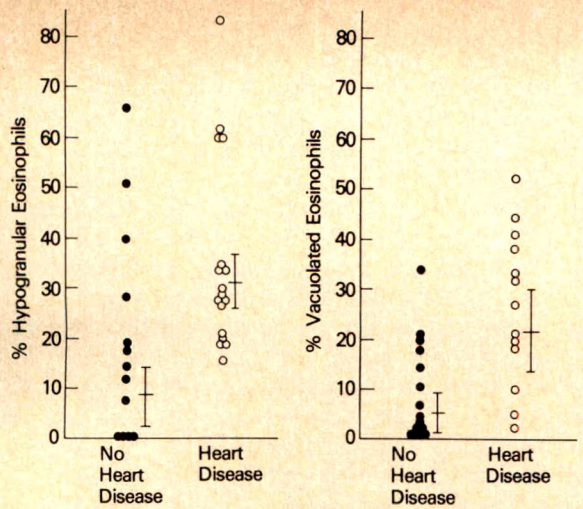

FIGURE 2. The proportion of hypogranular or vacoulated eosinophils at presentation was greater in the patients with heart disease (group I).

and frequency of anemia, were not significantly different between the 2 groups.

To develop the capacity to predict which patients were at risk for the development of heart disease, the earliest available morphologic material was reviewed (see Materials and Methods) and compared with the later clinical experience. The temporal sequence of splenomegaly and clinically detectable heart disease also was determined in each relevant case. An average of 32 ± 5% of the peripheral blood eosinophils were hypogranular in the patients who later developed heart disease (group I), whereas only 8 ± 6.5% were in group IV (Fig. 2). Vacuolated eosinophils were present in an average of 21 ± 8% of the peripheral blood eosinophils from group I and 3.8 ± 2.0% in group IV. The first available pretreatment platelet counts were substantially different, with an average of 168,000 ± 14,200 platelets/ml in group I and 414,000 ± 35,000 platelets/ml in group IV ($p < 0.001$). Abnormal erythrocyte morphology, myeloblasts, metamyelocytes, and myeloid dyspoiesis were more frequently found in the peripheral blood of the patients assigned to the group with overt clinical heart disease (Table V). Increased cellularity, fibrosis, and decreased megakaryocytes were more frequently found in the bone marrow at presentation in the patients with overt heart disease (group I).

In 8 of the 21 patients in group I it was possible to determine the order of appearance of splenomegaly and heart disease. In 6 of these 8, the splenomegaly preceded the heart disease, and in these patients an average of 10 ± 3 months (range 2 to 72) elapsed between the appreciation of splenomegaly and the onset of overt clinical heart disease. In 1 patient clinical heart disease clearly preceded splenomegaly by 27 months, and in 1 patient splenomegaly has not occurred 24 months after the onset of overt clinical heart disease. Thus, those patients with splenomegaly should be more carefully observed for the later development of heart disease.

The 2 women who developed heart disease were unusual. The first had severe bronchospasm and developed a dilated cardiomyopathy in conjunction with the eosinophilia. She was HLA-Bw44 positive but did not have splenomegaly or other characteristics of a myelo-

TABLE III Characteristics of the Patients Who Remained Free of Heart Disease

proliferative disorder. The second had a more typically myeloproliferative disease with splenomegaly and of advanced bone marrow disease. She was the only patient to have hypogranular and vacuolated eosinophils in the bone marrow as well as in the peripheral blood. However, this patient did not have the HLA-Bw44 haplotype.

Discussion

This analysis of a large population of patients with the idiopathic hypereosinophilic syndrome defines 2 patterns of clinical illness with respect to the development of heart disease. In one pattern, heart disease is accompanied by characteristics of a primary myeloproliferative type disease. These patients have splenomegaly, thrombocytopenia, and elevated serum vitamin B_{12}. They are more likely to have marrow fibrosis, immature myeloid forms, myeloid dyspoiesis, as well as abnormal eosinophil morphology in their peripheral blood.

Patients who have remained free of heart disease have characteristics of a more allergic or hypersensitivity process. They tend to have elevated Ig, especially IgE, and elevated levels of circulating immune complexes. In addition, all of the patients with angioedema are in this group.

Indeed, Löffler's original patients with this syndrome had splenomegaly along with their eosinophilia and cardiac involvement.[1] Particular attention was not focused on this association of splenomegaly with eosinophilia and heart disease until Shepard et al[12] pointed out the coincidence of these findings in their patients. Moreover, as we have shown herein, splenomegaly can predict the subsequent occurrence of overt clinical heart disease.

Other discriminating characteristics, in addition to splenomegaly, suggest a myeloproliferative syndrome in the patients who develop heart disease. The B_{12}-binding protein transcobalamin I is elevated in the myeloproliferative disorders and has been shown to be elevated in 1 patient with idiopathic hypereosinophilia. In addition, transcobalamin I has been found in eosinophils as well as neutrophils.[12,14] Except for an increased incidence of HLA-Bw44 and the sex ratio difference, the noncardiac associations that discriminate patients with heart disease from the remainder are all commonly recognized characteristics of myeloproliferative disorders.

Patients with HLA-Bw44 and idiopathic hypereosinophilia have an almost 4-fold increase in the risk of developing heart disease (Table III). The Bw44 haplotype was split from HLA-B12, which has been positively associated with follicular lymphoma, acute lymphoblastic leukemia, acute appendicitis, steroid responsiveness in nephrotic syndrome, and alopecia areata, and negatively associated with Buerger's disease and psoriasis vulgaris.[15] Perhaps the recently observed decreased responsiveness of lymphocytes from HLA-B12 donors to prostaglandin E_2 and histamine[16] is an important clue for these unexpected associations.

Our data establish the impression of earlier workers that those patients with idiopathic hypereosinophilia who develop heart disease have a poorer prognosis when compared with that of patients who remain free of heart disease[6,17,18] (Fig. 1). In addition, the improvement in morbidity and lifestyle of patients treated early in the course of their heart disease with appropriate medical and surgical management[19] emphasizes the importance of identifying predictive variables for and against the development of heart disease.

More monitoring. Less space.

One VSM®2 noninvasive vital signs monitor gives you the kind of patient monitoring you'd expect from a combination of three or four instruments.

It gives you ECG, heart rate, temperature, blood pressure, time, date. All documented. All in one. All visible at a glance.

And it gives you this vital information anywhere in the hospital because it's battery operated, compact, portable.

Use it alone. Or with our LIFEPAK®6s defibrillator/monitor or CMS™ 6000 central monitor.

Either way you'll find it answers your needs with total monitoring capability, dependable performance, and outstanding support worldwide.

Manufacturers of the LIFEPAK family of defibrillator/monitors.

A THERAPEUTIC STEP AHEAD

LOPID®
(gemfibrozil)

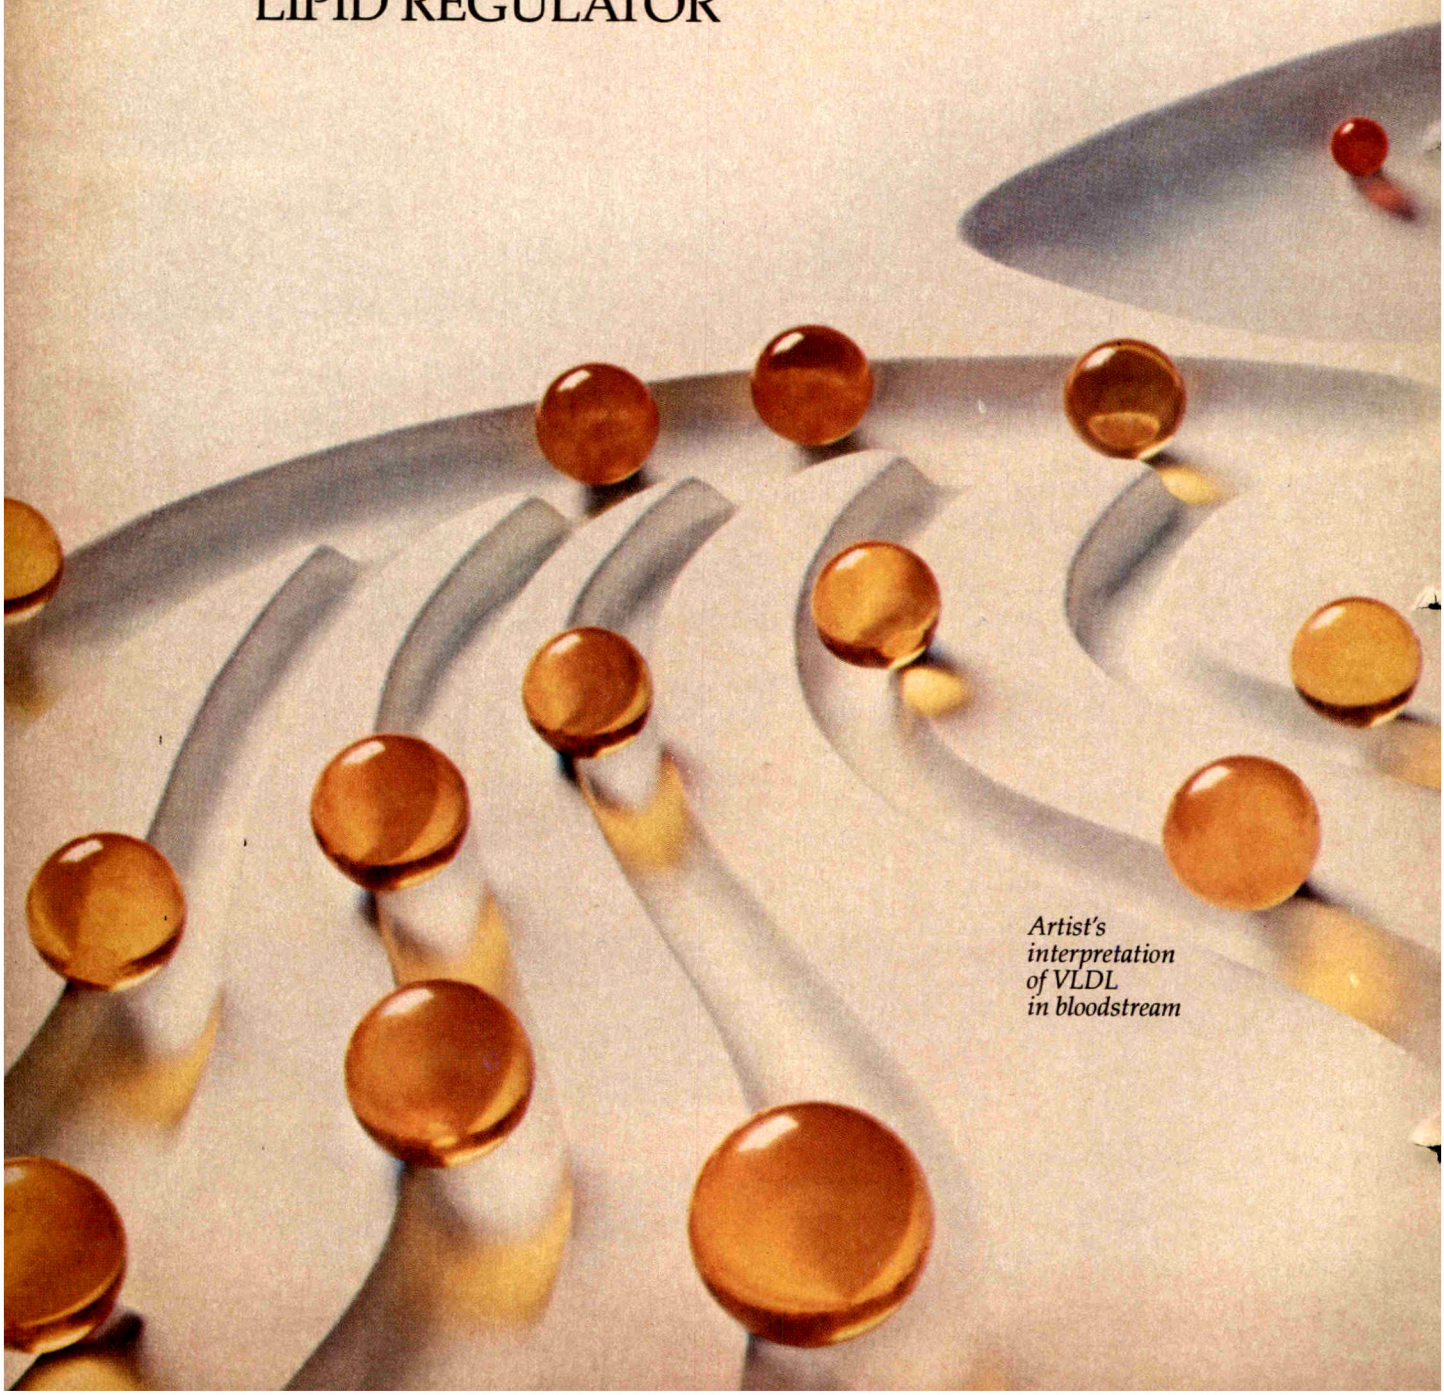
MORE THAN A LIPID-LOWERING AGENT— A TWO-WAY LIPID REGULATOR

Favorably regulates the balance of lipid fractions in certain dyslipidemias:

1/LOWERS elevated serum levels of triglyceride-rich VLDL and, to a lesser extent, cholesterol-rich LDL (very-low- and low-density lipoproteins implicated in dyslipidemia)

2/May also RAISE serum levels of HDL (high-density lipoproteins believed to transport cholesterol to the liver for catabolism and excretion)

LOPID is indicated for treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of pancreatitis and who do not respond adequately to diet.

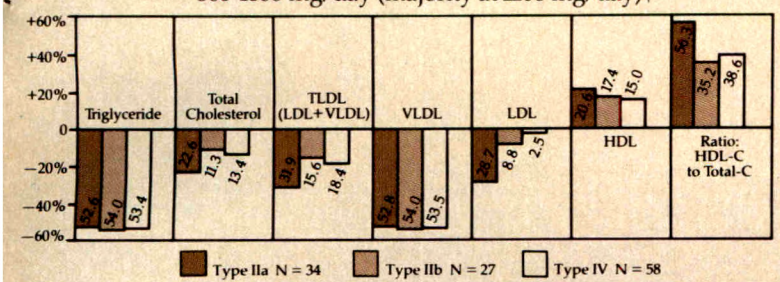


Artist's interpretation of VLDL in bloodstream

Lipid-regulating efficacy demonstrated in 1,437 patients with dyslipidemia[1]

Results of open-label phase of US multicenter study (119 patients) at end of 12 lunar months*

Average % change from baseline at doses ranging from 800-1600 mg/day (majority at 1200 mg/day)†



*Visit every 4 weeks during long-term use of LOPID.
†Data cited on this graph reflect clinical experience based on the multicenter trial. They do not imply an indication for Types IIa and IIb dyslipidemias.

Well tolerated, well accepted in clinical trials[1]

Profile of side effects similar to that of placebo.

No significant abnormalities seen in clinical and laboratory evaluations.

Less than 1% patient dropout in largest US study.

Convenient BID dosage

Diet, exercise, and weight loss are the first choice in therapy of lipid disorders.

LOPID®
(gemfibrozil)
A LIPID REGULATOR

LOPID® (gemfibrozil) Capsules

Before prescribing, please see full prescribing information.
A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO: HDL Cholesterol / Total Cholesterol
		Total	VLDL	LDL	HDL	
IIa	−44%	−4.2%	−44.3%	−5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	−6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (See WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis—LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy**—Before instituting LOPID (gemfibrozil) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy**—Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Seasonal Variation of Lipid Levels**—LOPID is not expected to alter seasonal variations of higher serum lipid values in mid-winter and late summer or the lower values in fall and spring.

4. **Impairment of Fertility**—Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. **Liver Function**—Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. **Cardiac Arrhythmias**—Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria
Central Nervous System: headache, dizziness, blurred vision
Musculoskeletal: painful extremities
Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia
Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints
Central Nervous System: vertigo, insomnia, paresthesia, tinnitus
Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)
Miscellaneous: fatigue, malaise, syncope

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

THE FUTURE HAS A WAY OF ECHOING THE PAST.

Today, we're EkoLine, one of the fastest growing companies in Echocardiography. But you probably knew us by our first name, Smith Kline Instruments. And no doubt, you know the reputation our M-mode systems have gained over the past 20 years. Most are still in operation. And most of you still won't give them up.

That's where we're coming from—over 20 years of experience and pioneering leadership in Echocardiography. If you were at ACC, you know where we're going.

History has a way of repeating itself.

The third issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

Cardiology 1983

What is CARDIOLOGY 1983?

- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1983 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

Lopressor®

metoprolol tartrate

is now

Once-a-day

New dosage schedule: To start, 100 mg once-a-day, or in divided doses
Dosage range: 100 mg – 450 mg daily

Lower doses (especially 100 mg) may not maintain full effect at end of 24-hour period. Measure BP near end of dosing interval, adjust to larger or more frequent dosage if needed.

*exerts a relative preference for beta-one receptors; this preference is not absolute

100-mg tablets

Please turn page for brief Prescribing Information.

Geigy

536-5763-A

metoprolol tartrate

An antihypertensive
beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

Two-Dimensional Echocardiographic Assessment of Surgically Closed Ventricular Septal Defect

JOSE L. ANDRADE, MD, WALTER SERINO, MD, MARC de LEVAL, MD, and JANE SOMERVILLE, MD

One hundred twenty patients operated on for closure of a ventricular septal defect (VSD) had postoperative assessment by 2-dimensional echocardiography. The presence of persistent "drop-out" between ventricular septum (VS) and the periphery of the "patch" was considered a sign of detachment and residual shunt. Echocardiographic findings of intact VS or residual VSD were correlated with angiographic findings in 30 patients and with clinical signs in 90 patients. Minute shunts with increased flow ratios <1.5:1 were occasionally missed. Persistent small drop-out was sometimes wrongly diagnosed as residual shunt when the patch was in an angled position and in the early postoperative weeks when peripatch edema of the VS suggested drop-out. Thus, 2-dimensional echocardiography is a reliable method for assessing significant persistent ventricular shunts and intact VS after surgical closure of a VSD.

After surgical closure of a ventricular septal defect (VSD), it is important to know that the defect has been completely closed, since this will influence symptoms and long-term advice.[1,2] When clinical signs suggest that a defect persists, invasive investigation has been used to determine the residual dynamics and anatomy. Contrast M-mode echocardiography has been useful in the immediate postoperative period to demonstrate residual shunt or adequate closure.[3] Now that real-time 2-dimensional (2-D) echocardiography is available for assessing the anatomy of the ventricular septum (VS),[4,5] it is an ideal method for assessment of the surgically closed VSD. The present study was undertaken in 120 patients who had been operated on for closure of VSD to assess the reliability of 2-D echocardiography in detecting persistent defects and complete surgical closure.

Methods

Patients: Between June 1981 and November 1982, 120 consecutive patients who had previous surgery for closure of VSD were assessed with 2-D echocardiography at the National Heart Hospital. Fifty patients had isolated VSD, and in 70 the VSD was part of a more complex cardiac malformation, such as Fallot's tetralogy (33), pulmonary atresia (14), atrioventricular defect (7), double-outlet right ventricle (5), transposition of the great arteries (4), corrected transposition of the great arteries (4), and truncus arteriosus (3).

An Advanced Technology Laboratory mechanical sector scanner MK300C using a 3.0-MHz transducer was used. Technically satisfactory visualization of the VS and the "patch," which appeared as an area of highly reflective echoes,[6] was required. Records were made from parasternal (4-chamber, long- and short-axis), apical (4-chamber), and subcostal (4-chamber and short-axis) planes.[7] The terminology used is as described by Capelli et al,[5] in which VSDs are classified as subvalvular, subdivided according to the valve they lie beneath (inlet, subtricuspid, subaortic, subpulmonary, and doubly committed subarterial), or muscular, subdivided according to where they are in the muscular ventricular septum (apical, central, and outlet).

Residual interventricular shunts were diagnosed on 2-D echocardiography when a partial detachment of the patch from the VS with systolic shift into the right ventricle was seen, with persistent echocardiographic drop-out between VS and the periphery of the patch. Based on the spatial orientation of the VS, the areas of drop-out were referred to as anterior, posterior, inferior (caudal), or superior (cephalic) (Fig. 1).

The rest of the VS was carefully profiled to look for a residual VSD which might have been missed at operation. Evidence of chamber enlargement was not used as a sign of persistent VSD, although it was noted. In the 120 patients the

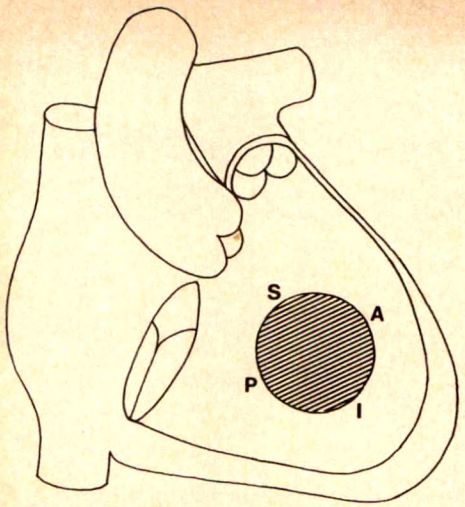

FIGURE 1. Diagram showing the main sites of a patch detachment. A = anterior; I = interior; P = posterior; S = superior.

site of the patches and the presence or absence of a residual VSD on 2-D echocardiography were interpreted by 1 of us, without previous knowledge of the clinical signs or of the postoperative angiographic findings (Table I).

Ninety patients had no invasive postoperative investigation, and 30 had cardiac catheterization with left ventricular angiography. The patients were divided according to the presence or absence of 2-D echocardiographic features of residual VSD, and these findings were correlated with physical signs and angiographic findings (Table II).

Results

Diagnosis of residual VSD by 2-D echocardiography: Thirty-four patients were considered to have a persistent VSD from the appearances on 2-D echocardiography. Sixteen of these had cardiac catheterization and angiography, and a residual ventricular shunt was shown in 13. In 3 patients, no evidence of interventricular shunts was found. Twelve of the 13 patients with angiographic confirmation of residual shunt have had reoperation, and the position of detachment was confirmed to be at the site suggested by 2-D echocardiography. No separate missed VSDs were found. Two-dimensional echocardiography was repeated after reoperation and confirmed an intact VS. In another patient, a reversed right-to-left shunt was found and reoperation was contraindicated. Contrast echocardiography in this patient had confirmed the right-to-left shunt through the reopened defect (Fig. 2). Eighteen patients in whom 2-D echocardiography suggested the presence of a persistent VSD had no invasive investigation. Physical signs of residual shunt were present in 14 of them and absent in 4. In these 4 patients 2-D echocardiography was performed within the first postoperative week.

The basic anatomy of the VSD in those in whom it was echocardiographically found to be opened was as follows:

Inlet: Four patients had a residual VSD in this area. The residual defect appeared in 4-chamber view as a detachment between the posteroinferior part of the patch and the crest of the septum (Fig. 3). This was confirmed angiographically and at reoperation in 2 patients.

Subtricuspid: Nine patients with patched subtricuspid VSD had detachment in the inferoposterior part of the VS seen in 4-chamber view (Fig. 4). This was confirmed by angiography and reoperation in 3.

Subaortic: Sixteen patients with persistent defect had had patching of a large subaortic VSD. In 11, the long-axis view of the left ventricle showed a discontinuity between the anteroinferior part of the patch and the crest of the VS (Fig. 5A). This was confirmed by angiography in 3 and at reoperation in 2. In 5 patients the drop-out appeared anterosuperiorly between the patch and the anterior wall of the aorta (Fig. 5B). This was confirmed by angiography and at reoperation in 2.

* Patients with postoperative invasive investigation.
† Patients without invasive investigation.
VS = ventricular septum; VSD = ventricular septal defect.

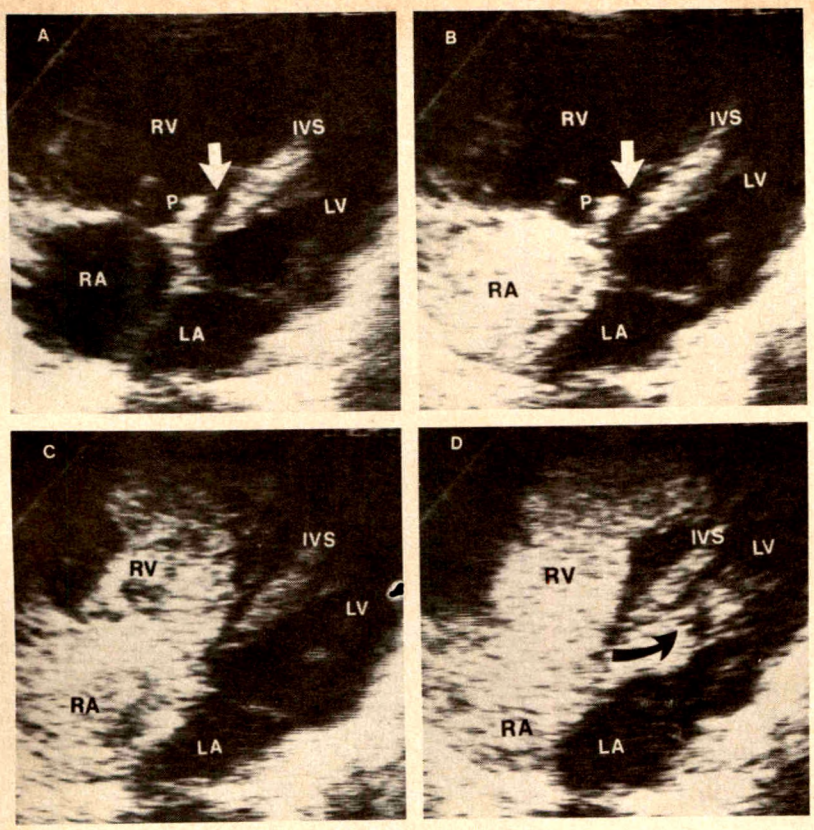

FIGURE 2. Contrast 2-dimensional echocardiograms from a patient with a patched subaortic VSD and clinical and angiographic signs of an irreversible right-to-left ventricular shunt. **A,** parasternal 4-chamber view before the contrast injection showing a persistent inferoposterior VSD (**white arrow**). **B,** contrast echoes filling the right atrium (RA). **C,** contrast echoes have passed from the right atrium into the right ventricle (RV). **D,** contrast echoes have passed from the right ventricle into the left ventricle (LV) during ventricular systole (**black arrow**). The left atrium (LA) remains free of contrast echoes. IVS = interventricular septum; P = patch.

Muscular: Five patients with patched muscular defects had obvious detachment of the patch which was present inferiorly in 4-chamber view (Fig. 6). This was confirmed by angiography and at reoperation in 3.

Diagnosis of intact VS by 2-D echocardiography: In 86 patients the VS appeared on 2-D echocardiography to be intact. In these patients, the patched VSD was inlet (7), subtricuspid (15), subaortic (47), muscular (9), subpulmonary (3), or doubly committed subarterial (5).

Fourteen had cardiac catheterization and angiography, and no residual shunt was found in 12. A minute jet of contrast medium was seen in the subtricuspid area in 1 patient and in the subaortic area in 1. No surgery was indicated in these 2 patients because the shunts were minute.

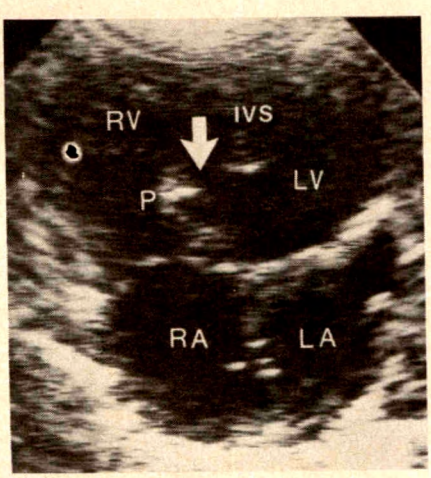

FIGURE 3. Two-dimensional echocardiographic apical 4-chamber view from a patient in whom inlet VSD has been patched but residual inferoposterior VSD persisted (**arrow**), confirmed angiographically and by surgery. IVS = interventricular septum; LA = left atrium; LV = left ventricle; P = patch; RA = right atrium; RV = right ventricle.

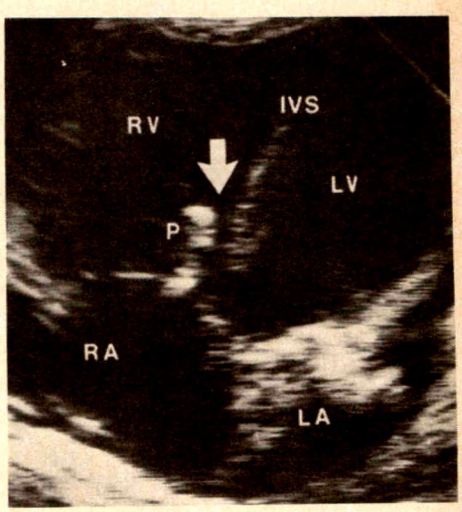

FIGURE 4. Two-dimensional echocardiographic apical 4-chamber view from a patient in whom a subtricuspid VSD has been patched, but a residual inferoposterior VSD persisted (**arrow**), confirmed angiographically. IVS = interventricular septum; LA = left atrium; LV = left ventricle; P = patch; RA = right atrium; RV = right ventricle.

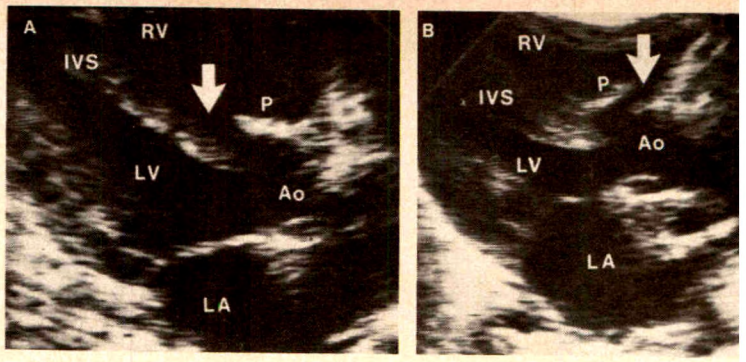

FIGURE 5. Two-dimensional echocardiographic parasternal long-axis view in 2 patients in whom subaortic VSDs had been patched but residual anteroinferior (**A**) and anterosuperior (**B**) VSDs persisted (**arrows**), both confirmed angiographically and by surgery. Ao = aortic valve; IVS = interventricular septum; LA = left atrium; LV = left ventricle; P = patch; RV = right ventricle.

Sixty-nine of the 72 patients with neither echocardiographic signs of residual VSD nor invasive investigation had no clinical sign of persistent VSD. Three had a pansystolic murmur suggesting a residual shunt, but no drop-out was seen around the patch, nor could another defect be seen.

Discussion

Two-dimensional echocardiography has been shown to be a good method for displaying dense structures such as a Dacron® patch inside the heart. The position of the patch on the VS delineates the anatomic type of defect because the patch shows brighter echoes than the VS and the interface between them is easily visualized.

In 15 patients with angiographic proof of residual shunt the 2-D echocardiogram was correct in 13 (86%). In the 2 patients in whom the VSD was not detected by 2-D echocardiography, the measured shunts were <1.5:1 and so the defect, although present, was hemodynamically insignificant. Among the 17 patients with clinical signs of residual shunt who did not undergo invasive investigation, 2-D echocardiography showed signs of detachment in 14 (82%), suggesting that 2-D echocardiography was correct. In the 3 patients in whom 2-D echocardiography had not shown a residual VSD although clinical signs suggested its presence, the leaks may have been too minute to be detected.

Small leaks underneath the patch due to loose stitches or detachments which are smaller than the resolution power of the ultrasound beam could not present any detectable echocardiographic drop-out.

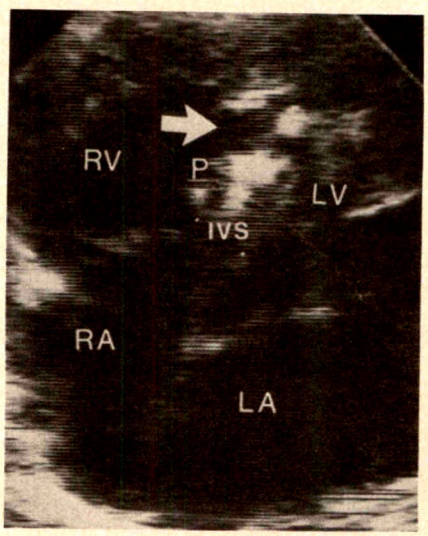

FIGURE 6. Two-dimensional echocardiographic apical 4-chamber from a patient in whom a central muscular VSD had been patche residual posteroinferior VSD persisted (**arrow**), confirmed a graphically. IVS = interventricular septum; LA = left atrium; LV ventricle; P = patch; RA = right atrium RV = right ventricle.

In the 73 patients with no clinical sign of resi shunt who did not have postoperative invasive in tigation, 2-D echocardiography showed no VSD in thus, the echocardiographic diagnosis of intact was correct in 94%. In 4 false-positive cases, 2 prese an important malalignment of the septum and

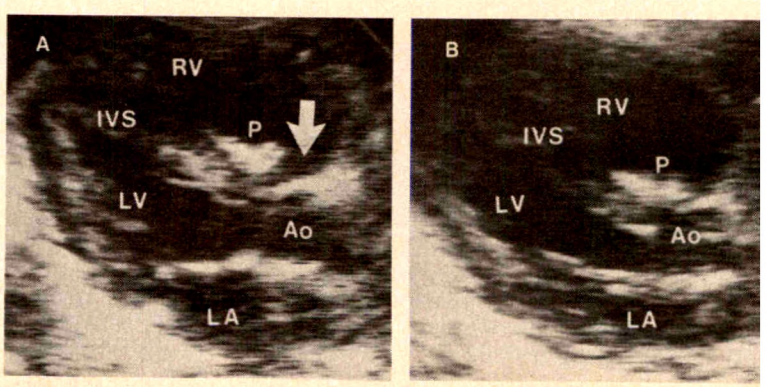

FIGURE 7. Two-dimensional echocardiographic parasternal long-axis view from a patient with patched subaortic VSD and no clinical signs of residual shunt. **A,** immediate postoperative assessment showing a drop-out between the patch (P) and the anterior wall of the aorta (Ao). **B,** 2 months later, the drop-out had disappeared. IVS = interventricular septum; LA = left atrium; LV = left ventricle; RV = right ventricle.

echocardiography was done in the immediate postoperative period.

Of 15 patients in whom angiography showed an intact VS, 2-D echocardiography predicted that this was correct in 12 (80%). In 1 patient the patch was in an angled position, giving the appearance of discontinuity between septum and patch. In 2 patients studied in the first postoperative fortnight, there was a persistent drop-out between VS and patch. The patients were restudied 1 to 2 months later and the echocardiographic drop-out had disappeared (Fig. 7). This false-positive echocardiographic appearance was probably peripatch edema of the VS or hematoma. It is possible that pulsed Doppler echocardiography[8] will provide additional information for detecting small shunts in patients who have physical signs of residual VSD but nothing obvious on 2-D echocardiography, and for ruling out shunts in those who have no clinical signs of residual VSD but echocardiographic drop-outs suggesting VSD. Although minute VSDs were missed, real-time echocardiography has been a reliable noninvasive technique for detecting significant residual shunt and intact VS after surgical closure of VSD.

Postmortem Digoxin Tissue Concentration and Organ Content in Infancy and Childhood

ALOIS R. HASTREITER, MD, and RONALD L. VAN DER HORST, MD

The concentration of digoxin in tissues and the content of the drug in various organs are reported in 36 infants and children. Sixteen received the drug on a short-term basis and 20 on a long-term basis. The drug was given intravenously to 12, orally to 17, and by intramuscular injection to 7. The study was conducted to determine distribution of digoxin in infants and children and to examine the forensic implications related to digoxin overdosage. Upper therapeutic concentration thresholds for digoxin were established in various tissues. These are different for preterm and full-term neonates than for older children and adults; for example, adult and neonatal values for postmortem blood specimens are 8 and 15 ng/ml, and for ventricular myocardium are 250 and 450 ng/g, respectively. The chronically digitalized premature infant retains in most tissues a considerably larger fraction of digoxin than more mature infants and children. This is in accord with previously demonstrated lower renal digoxin levels in premature infants attributed to their reduced ability to excrete this drug.

Tissue concentrations of digoxin have been reported in few infants and children.[1–6] Variables that affect the tissue concentration of digoxin include age, dosage, duration of treatment, and route of administration. We present the tissue concentrations of digoxin at autopsy in 36 infants and children, 16 of whom received the drug on a short-term and 20 on a long-term basis. The data are important in understanding the distribution of digoxin in different age groups, and for forensic purposes.

Methods

Thirty-six patients aged 1 day to 18 years who received digoxin and died from congenital heart disease were studied. None had clinical or electrocardiographic signs of toxicity. Blood and tissue samples from various organs were obtained at autopsy according to a specific protocol. Serum digoxin concentrations were measured within several days before death and within 24 hours after death. The digoxin concentration in each organ was measured by previously reported methods[2,3] and was expressed as nanograms/gram of wet tissue or nanograms/milliliter of blood or bile. The patients were subdivided into a short-term (acute) group (AcG) who received the drug for ≤3 days (n = 16) and a long-term (chronic) therapy group (ChrG), who received it for >3 days (n = 20). They were further subdivided into groups representing age and maturity, such as premature neonates (n = 12), full-term neonates (n = 12), children <2 (n = 5), and children >2 years (n = 7), and into groups receiving intravenous (n = 12), oral (n = 17), or intramuscular (n = 7) digoxin.

Pertinent clinical data and digoxin dosage are shown in Table I. Postmortem content of digoxin in various organs was calculated by multiplying the tissue concentration of the drug by the organ weight. The weights of the heart, kidneys, liver, spleen, lungs, brain, adrenal glands, and pancreas were measured directly at autopsy. The weights of blood volume, skeletal muscle, skin, fat, stomach, small and large intestines, gall bladder, bile, urinary bladder, thymus, thyroid, and gonads were derived from standard reference tables applicable to our age and weight groups.[7] Samples from brain, kidney, and adrenal glands were obtained from the cortical area. Statistical analysis included paired and unpaired t tests to determine differences between groups.

Results

Digoxin tissue concentrations are shown in Table II and the organ content of digoxin in Table III.

Digoxin tissue concentrations: The digoxin concentration of postmortem blood samples was always higher than that in premortem samples. In premature and full-term neonates, pre- and postmortem blood digoxin concentration tended to be higher than that of older children in both the AcG and ChrG. The highest values were 4.0 ng/ml in premortem and 14.1 ng/ml in postmortem blood samples, both from premature infants. Four preterm infants had premortem blood levels

Admin = administration; BSA = body surface area; IM = intramuscular; IV = intravenous; PO = oral; SD = standard deviation.

≥3 ng/ml (3.0, 3.5, 3.9, and 4.0), and 3 had a postmortem digoxin concentration >10 ng/ml (12.0, 14.1, and 11.5). Three full-term neonates had premortem blood levels ≥3.0 ng/ml (3.0, 3.2, and 3.7) and only 1 had a postmortem blood digoxin concentration of >10 ng/ml (12.7).

In right (RV) and left (LV) ventricular myocardium, the digoxin concentration was not significantly different in the AcG. In the ChrG, the RV concentration tended to be lower than the LV, but this was not evident in all subsets. In both short- and long-term groups, myocardial digoxin concentration was lower in older children compared with preterm and full-term neonates. No statistically significant difference occurred between the myocardial concentrations in the latter 2 groups. In 1 premature infant, both LV and RV myocardium had a digoxin concentration of >400 ng/g (456 and 431 ng/g, respectively). This also occurred in the left ventricle of 1 full-term neonate (450 ng/g). Average values for LV and RV digoxin concentration were more than 150 ng/g in all neonates. In children <2 years of age, the mean RV and LV digoxin concentration values were >125 and 150 ng/g, respectively. In older children, myocardial digoxin levels in the AcG were about 100 ng/g and those in the ChrG were lower. Digoxin levels in atrial myocardium were generally lower than those in ventricular myocardium.

Renal digoxin concentration showed great variability and no significant age differences in the ChrG. Mean values were 131 to 291 ng/g. Older children had similar renal digoxin values in the AcG and ChrG; however, in premature infants in the AcG these values were significantly lower (mean 71 ng/g).

Skeletal muscle and skin digoxin concentration showed no significant differences between AcG and ChrG and among the various age groups; mean values were 17 to 48 ng/g in the former and 9 to 35 ng/g in the latter. Adipose and splenic tissue digoxin levels were low (11 and 18 ng/g, respectively) in all age groups and subsets.

The digoxin concentration in lung tissue ranged from 26 to 37 ng/g except in the older children in the ChrG, in whom it was 12 ng/g. Adrenal cortical digoxin levels tended to be lower in older children in the ChrG but not in the AcG. In urinary bladder, thymus, thyroid, and gonad (of either sex) samples, the digoxin concentration did not show appreciable difference with age in the AcG; in the ChrG, it tended to be lower in older children. The digoxin concentration in cerebral cortex specimens was low, usually <20 ng/g. It was lower in AcG than in ChrG and there was no significant difference between age groups. In the liver and hollow gastrointestinal viscera (stomach, small and large intestine, and gall bladder), the digoxin levels were variable. They were lower in older children. The highest values were found in small intestine and gall bladder.

Digoxin content of organs: The postmortem digoxin content of the organs was expressed as a percentage of the dosage administered. For the AcG, the total loading dose of digoxin was used as a reference; for the ChrG, the daily maintenance dose was used.

Acute group: In preterm infants, an average of 59% of the total dose of digoxin administered was recovered from the body tissues analyzed; in full-term neonates, 52% was recovered and in older children, 73% of digoxin was recovered. The differences between age groups were not statistically significant.

Most digoxin was recovered from skeletal muscle, that is, one fifth to one third of the dose administered; significant amounts were also extracted from heart (4 to 7%), kidneys (2 to 4%), skin (3 to 6%), fat (2 to 7%), lung (2 to 3%), brain (2%), and blood (0.4 to 1%) samples. In the gastrointestinal tract, values were liver 5 to 7%, pancreas 0.2 to 1%, stomach 0.2 to 0.4%, small intestine

3 to 6%, large intestine 0.3 to 1%, and gall bladder 0.3 to 0.2%. The spleen, adrenals, urinary bladder, thymus, thyroid, and gonad each contained <1% of the total dose administered.

Chronic group: The total amounts of digoxin recovered from the various organs analyzed, expressed as a percentage of the daily maintenance dose, were 458% in preterm infants, 144% in full-term neonates, 118% in children under 2 years, and 199% in older children. Premature infants retained a significantly greater fraction of the daily maintenance dose. In the ChrG, large quantities of digoxin were found in skeletal muscle (145% in premature infants and 38 to 124% in the older age groups), heart (83% in premature infants and 4 to 15% in older children), kidneys (25% in premature infants and 8 to 13% in older children), skin (32% in premature infants and 8 to 9% in older infants), fat (24% in premature infants and 6 to 9% in older children), brain (17% in premature infants and 9 to 15% in older children), and blood (3% in premature infants and 0.5 to 1% in older children) specimens.

The organs of the gastrointestinal tract also contained significant amounts of digoxin: liver (57% in premature infants and 13 to 20% in older children), pancreas (1% in premature infants and 0.2 to 1.4% in older children); stomach (3% in premature infants and 1% in older

wet tissue except for blood and bile, which are expressed as nanogram/milliliter.

children); small intestine (42% in premature infants and 4 to 6% in older children); large intestine (1% in premature infants and 1 to 6% in older children); gall bladder (0.3% in premature infants and 0.03 to 0.1% in older children); and bile (1% in both premature infants and older children). Other organs (adrenal glands, urinary bladder, thymus, thyroid, and gonads) each contained ≤1% of the maintenance dose of digoxin administered.

Effect of dosage, route, and duration of administration: It was not possible to determine significant differences of tissue distribution with respect to the route of administration and dosages given. Premature and full-term neonates in the AcG tended to have lower values than those in the ChrG; this was not observed in older children.

Discussion

The present data improve the understanding of the body distribution of digoxin in infants and children and the forensic medical aspects of fatal overdosage of the drug. Previous information regarding digoxin tissue concentrations and organ contents in the pediatric age group has been fragmentary.[1–6]

Significant differences exist between serum digoxin concentration obtained pre- and postmortem,[8] and the

latter may show significant site variability. In adults, the mean post- to premortem digoxin concentration ratio was 1.96 to 2.33 for heart, 1.63 for subclavian, 1.38 to 1.42 for femoral, and 1.84 for jugular venous blood specimens.[8,9] No significant differences were found between pre- and postmortem blood samples obtained ≤30 minutes after death.[10] For longer periods, no correlation was observed between postmortem period and blood digoxin concentration; this suggested that a new equilibrium is established after death.[8,10]

The mean digoxin concentration ratio between whole blood and serum was 1.3[11]; this reflects the binding of most glycoside to the erythrocyte membrane. The erythrocyte: plasma digoxin ratio is less in the AcG than in the ChrG, 1.00 ± 0.43 and 3.62 ± 2.00 (± standard deviation), respectively.[6]

In 1969, Hernandez et al[1] studied the pharmacodynamic features of digoxin in infants using tritiated digoxin. These radioisotope data, although extremely useful with regard to kinetics, cannot be readily converted into tissue concentrations. Our own laboratory reported tissue concentrations of digoxin obtained at surgery in 1974[2] and autopsy in 1975[3] in infants and children. Neonates had higher concentrations in the RV and LV myocardium than older children and adults. Renal concentrations were lower in preterm than full-term neonates and older children. Andersson et al[4] published data on tissue levels in 12 infants and 17 adults. The digoxin concentration was significantly higher in myocardium and kidney samples from infants.

Lang et al[5] in 1978 reported tissue and plasma digoxin levels in 13 premature and 6 full-term newborns, and 5 older infants. Tissue digoxin levels tended to be higher in premature and full-term newborns than in mature infants. This difference was statistically significant in myocardium and skeletal muscle. The renal digoxin concentration was lower in premature than in mature neonates; the tissue concentrations of other organs were essentially equal in these groups. No significant difference in the ratio of myocardium and plasma digoxin was found among the various age groups.

Gorodischer et al[6] in 1976 examined the distribution of digoxin in myocardium skeletal muscle, and plasma in 8 infants and children and the digoxin concentration in erythrocytes and plasma in 16 patients. Some of the values for myocardium, skeletal muscle, and serum concentrations were considerably higher than those observed by other investigators. The mean myocardial digoxin concentration was 386 ng/g; it was ≥483 ng/g in 4 of the 8 children studied. The highest myocardial concentration was 975 ng/g. These data can probably be explained by the short dose-autopsy interval (0.75 to 6 hours) and the large digitalizing doses given.[6]

In the present study, neonates who received therapeutic doses of the drug had higher levels in several tissues than older children. These differences were especially striking for myocardium, liver, and the gastrointestinal tract. Digoxin concentrations in the AcG tended to be lower than those in the ChrG in premature and full-term infants, but not in older children. The digoxin concentration in premortem blood samples was <4 ng/ml in infants and <2 ng/ml in older children. Postmortem blood samples obtained from the heart had maximal levels of <15 ng/ml in neonates and <5 in older children. Ventricular myocardial digoxin levels were generally >200 ng/g in neonates, but measured 160 to 180 ng/g in AcG preterm infants. Older children had levels of ≤100 ng/g. Acutely digitalized premature infants had lower renal digoxin levels, because of their reduced ability to excrete the drug. No significant differences in renal digoxin levels were noted among the other age groups. Because of the variability of its digoxin concentration, the kidney does not represent a good organ from which to judge toxicity.

Skeletal muscle is the major repository for digoxin and, as shown in this study, its digoxin concentration has a narrow range. Liver tissue is another useful marker of digoxin toxicity. Lung digoxin levels are low in chronically digitalized children, but are higher in full-term neonates, especially premature infants. This may be related to the greater compactness of premature lung tissue. The concentration of digoxin in the gastrointestinal tract varies markedly and is often high even when the drug is administered parenterally. In adults, as much as 30% of a digoxin dose may be excreted in the bile within 24 hours, resulting in a significant enterohepatic cycle.[12,13] Digoxin excretion into the bowel, through the bowel wall itself, has also been proposed.[13]

Digoxin is concentrated in specific areas of the brain, for example, the choroid plexus of the fourth ventricle.[14] In cases of toxicity, digoxin may also be concentrated in other areas, such as the area postrema (chemoreceptor trigger zone) nucleus of the vagus and optic apparatus.[15,16] This distribution may explain symptoms of digoxin toxicity.

With chronic digoxin administration, the amount of drug retained in the tissues was strikingly higher in preterm infants—from 4 to 5 times the daily maintenance dose—than in older children, who retained 1 to 2 times this dose.

Doherty et al[17] reported the half-time of digoxin distribution in tissue samples to be 30 minutes after intravenous administration and 50 minutes after oral ingestion in liquid form. As a consequence, one would expect, after an intravenous dose, that 50% of the maximal concentration would occur in the tissues by 0.5, 75% by 1, and 94% by 2 hours.

Reissel et al[18] considered levels of ≥8 ng/ml in postmortem blood samples and ≥250 ng/g in ventricular myocardium specimens to represent toxic levels in adults. On the basis of the present data, the corresponding toxic postmortem concentrations in neonates are much higher, that is, 15 ng/ml in postmortem blood samples, and 450 ng/g in ventricular myocardium specimens. In the absence of blood or myocardium, liver and skeletal muscle are the alternative tissues of choice for toxicologic analysis of digoxin. Kidney tissue is not a reliable indicator of toxicity. Spiehler et al[14] suggested that the digoxin content of medulla, under the obex, may be useful in confirmation of the elevated blood digoxin concentration.

The present study enlarges on reports of tissue distribution of digoxin: the limits of toxicity in infants and children can be determined with greater confidence based on this larger and more comprehensive series.

Masked Subaortic Stenosis in Ostium Primum Atrial Septal Defect: Recognition and Treatment

RHONDA S. LAPPEN, MD, ALEXANDER J. MUSTER, MD, FAROUK S. IDRISS, MD, THOMAS W. RIGGS, MD, MICHEL ILBAWI, MD, MILTON H. PAUL, MD, SAROJA BHARATI, MD, and MAURICE LEV, MD

Five patients with ostium primum atrial septal defect (ASD) and a cleft mitral valve had no hemodynamic evidence of left ventricular (LV) outflow tract obstruction on preoperative cardiac catheterization. After surgical closure of the ASD and repair of the mitral cleft, all 5 patients manifested subaortic stenosis with pressure gradients ranging from 10 to 120 mm Hg. Postoperative LV angiograms revealed systolic narrowing of the outflow tract, and the same outflow tract dynamics were recognized on reviewing the preoperative angiograms and echocardiograms. Persistence or exaggeration of the characteristic diastolic "goose-neck" deformity during LV systole in atrioventricular canal defects is diagnostic of a potential or actual subaortic obstruction. This diagnostic sign is also readily recognizable by 2-dimensional echocardiography, and when present, the surgeon should be alerted to explore the LV outflow tract because the outflow tract anatomy is not readily apparent at operation aimed solely at closing the ASD and repairing the cleft mitral valve.

Hemodynamic masking of left ventricular (LV) outflow tract obstruction by a large ventricular left-to-right shunt has been recognized as a diagnostic pitfall in congenital cardiac defects.[1,2] In contrast, the only known entity with intact ventricular septum in which stenosis of the LV outflow tract can be hemodynamically inapparent is ostium primum atrial septal defect (ASD) with a cleft mitral valve. Although mild LV outflow tract pressure gradients have been noted infrequently in ostium primum defects before intracardiac repair,[3,4] subaortic stenosis (SAS) is more readily recognizable during postoperative cardiac catheterization[5,6] or at autopsy.[7] In most such patients, anatomic narrowing of the LV outflow tract is already present preoperatively and can be recognized by angiography[3] and echocardiography.

Methods

Between 1975 and 1981, 5 patients who presented with SAS after surgical repair of ostium primum ASD and cleft mitral valve were identified (Table I). In none of the 5 patients was SAS diagnosed before corrective surgery; however, a review of the preoperative angiograms (Fig. 1) in all 5 patients and the preoperative echocardiograms (Fig. 2) in 2 patients revealed anatomic features of the LV outflow tract that are characteristic of this variant of ostium primum defect.[3] Similarly, in none of the 5 patients was the LV outflow tract obstruction detected during initial surgical repair.

A prominent postoperative systolic murmur attributed clinically to residual mitral regurgitation prompted cardiac catheterization in all 5 patients an average of 4 years after primary surgical repair. Mitral regurgitation was mild in 2 patients, minimal in 1, and undetectable in 2 (Table I). However, unexpected pressure gradients across the LV outflow tract ranging from 10 to 120 mm Hg (mean 56) were found in all to explain the postoperative murmur. In 4 patients who had postoperative 2-dimensional echocardiograms, the LV outflow tract was tunnel-like, with systolic narrowing in 3 and, in addition, anomalous mitral valve attachments to the ventricular septum were noted in the fourth patient. Persistence of the goose-neck deformity during ventricular systole was observed in these patients both angiographically and echocardiographically. In 2 patients (DCA, DT) who had this typical systolic goose-neck deformity on preoperative angiograms, additional discrete stenosis of the LV outflow tract was evident postoperatively (Fig. 3), requiring reoperation.

FIGURE 1. Systolic goose-neck narrowing in preoperative left ventricular cineangiograms. **Top,** anteroposterior view (patient BD). **Bottom,** lateral view (patient DCH). **Arrows** indicate systolic increase in outflow tract narrowing. D = diastole; S = systole.

We surveyed preoperative LV angiograms in 22 additional unselected patients who had surgery to correct the ostium primum defect over the past 10 years. Three patients had no narrowing of the LV outflow tract throughout the cardiac cycle, 18 had the common diastolic goose-neck deformity, and only 1 patient had unequivocal dynamic systolic narrowing of the outflow tract. This same patient was catheterized after repair of the ostium primum defect and had no subaortic pressure gradient; angiographically, systolic narrowing of the LV outflow tract was no longer observed.

Surgical approach: Three patients had reoperation for hemodynamically significant SAS (Table I). Septal myotomy or myectomy, or both, was carried out in an attempt to enlarge the outflow tract in all 3 patients, and in 2, an additional fibromuscular ridge was resected. In the patient with the most severe SAS (DCH), cardiac catheterization and echocardiography after the first reoperation revealed marked residual SAS due to an excessively anterior attachment of the anterior mitral leaflet. At a second reoperation, the superior portion of the anterior mitral leaflet was detached from its original attachment to the crest of the ventricular septum and retracted posteriorly to create a large gap between the outflow septum and the valve leaflet. This gap was bridged with a pericardial patch which in effect relocated the mitral valve insertion posteriorly and thus enlarged the outflow tract. Because of an episode of endocarditis 2 months later, the mitral valve was replaced. An echocardiogram confirmed that the outflow tract has remained unobstructed 3 years after the last operation and the patient has remained symptom free.

Autopsy findings: A survey of anatomic specimens revealed 25 specimens of ostium primum ASD with associated anatomic narrowing of the LV outflow tract.[8] In 13 unoperated specimens, the narrowing was caused by an aneurysm of the membranous septum (1 specimen), excessive endocardial and

chordal tissue (2 specimens), abnormal mitral valve attachments (4 specimens), generalized outflow tract hypoplasia (2 specimens) with additional anomalous mitral valve attachments (3 specimens), and an anomalous muscle bundle (1 specimen). In 12 postoperative specimens, the factors responsible for outflow narrowing were a discrete fibroelastic ridge (1 specimen), anomalous muscle bundle (2 specimens), abnormal mitral valve attachments (1 specimen), excessively reduced subaortic area after suture-closure of the large mitral cleft (7 specimens), and obstructive mitral prosthesis (1 specimen).

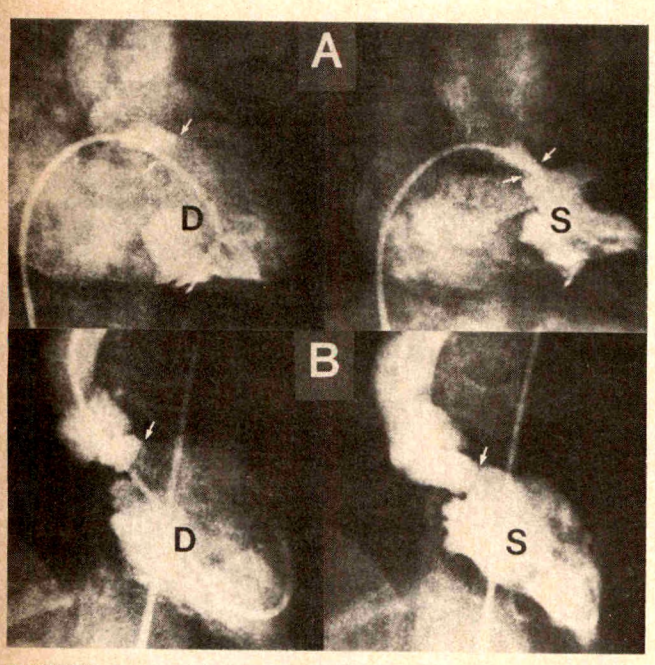

FIGURE 3. Left ventricular cineangiograms (anteroposterior view) in patient DCA. **A,** preoperatively, severe systolic outflow tract narrowing occurs simultaneously with massive mitral regurgitation; no subaortic pressure gradient is recorded. **B,** 5 years postoperatively, there is no mitral regurgitation and an 80 mm Hg pressure gradient is recorded across a discrete outflow ridge. **Arrows** indicate site of stenosis. D = diastole; S = systole.

Discussion

In this report, the term *ostium primum ASD* and the more anatomically appropriate terms *partial atrioventricular canal* and *partial atrioventricular septal defect*[9] are used interchangeably.

Because of the characteristic deficiency of the ventricular septum in atrioventricular canal defects and the abnormally anterior insertion of the mitral valve,[10] the outflow tract in ostium primum ASD becomes distorted, elongated, and narrowed (Fig. 4). The degree of this narrowing depends on the extent of septal deficiency, and in severe cases as much as three eighths of the septum may be absent.[11] In some patients the only remaining septum at the base is the conus septum.

The excavated smooth muscular septum and the abnormal mitral valve insertion produce the characteristic goose-neck appearance of the LV outflow tract during diastole in angiograms and echocardiograms. The extent of LV septal excavation and the potential for SAS can be assessed angiographically by the dynamics of the goose-neck deformity during the cardiac cycle (Fig. 5). Infrequently, an ostium primum defect with minimal septal excavation will have no goose-neck deformity in either diastole or systole (Fig. 5A). However, in most ostium primum defects, a moderate degree of septal excavation is reflected in a goose-neck deformity limited to diastole (Fig. 5B). In patients with more extensive outflow tract excavation and distortion who are at risk of developing SAS postoperatively, the diastolic goose-neck narrowing persists or becomes even narrower during systole (Fig. 5C). However, unless a critical point in this narrowing is reached, some patients in this category may not demonstrate resting LV outflow pressure gradients after repair of an ostium primum defect.

Preoperative hemodynamics in ostium primum defect apparently mask the severity of SAS even in patients in whom the LV outflow tract becomes critically narrowed during systole. After surgical repair of ostium

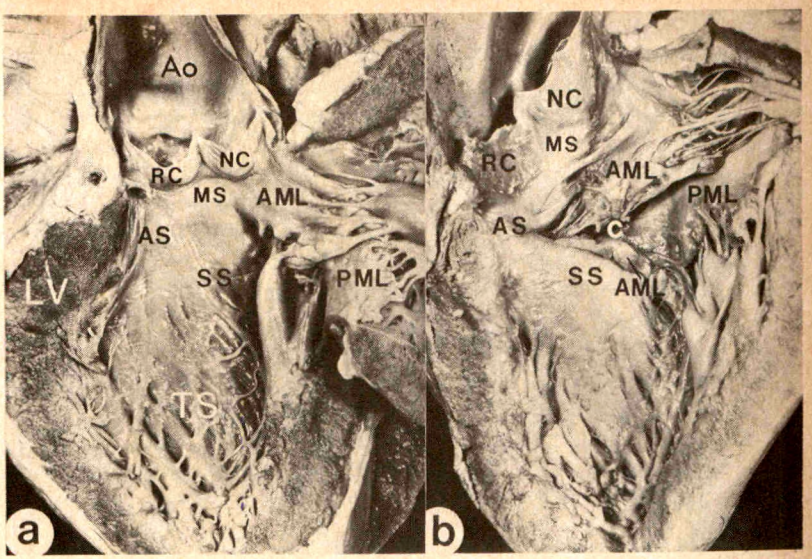

FIGURE 4. Left ventricular septal and outflow tract anatomy. **a,** normal heart demonstrating that the smooth sinus septum (SS) forms a major portion of the outflow area. **b,** in partial atrioventricular canal with severe deficiency of the smooth sinus septum, there is a large gap in the outflow tract which is filled by the anteriorly attached anterior mitral leaflet, producing subaortic narrowing. AML = anterior mitral leaflet; Ao = aorta; As = anterior septum; C = cleft; LV = left ventricular free wall; MS = membranous septum; NC = noncoronary cusp; PML = posterior mitral leaflet; RC = right coronary cusp; TS = trabeculated septum.

primum defect with a cleft mitral valve, the following mechanisms may contribute to the development of LV outflow tract pressure gradients: (1) The creation of a less mobile single valve leaflet from freely mobile cleft components may significantly limit the systolic travel of the anterior mitral leaflet from its diastolic position in the narrow outflow tract. (2) In the preoperative state, anomalous chordal or papillary muscle attachments of the cleft leaflets to the septum may not restrict leaflet mobility significantly; however, after cleft repair, the surgically fashioned single leaflet is more likely to remain anchored in the outflow tract by these attachments throughout the cardiac cycle. (3) Closure of the cleft and of the ASD eliminates the systolic LV vent to the right atrium and may produce an outflow pressure gradient by similar changes in hemodynamics, as observed in occult SAS after closure of a large ventricular septal defect.[1] (4) Significant mitral regurgitation reduces the effectiveness of the left ventricle as a forward pump; after cleft repair, the improved forward output and the increased systolic velocity of blood flow in the narrowed outflow tract may unmask a potential stenosis. (5) An obstructive fibrous ridge may develop postoperatively on the septal surface of a significantly narrow outflow tract as a result of increased turbulent flow and can in time produce pressure gradients.[3] (6) Any additional abnormality in the outflow tract (e.g., excessive septal bulge,[12] primary discrete SAS, aneurysm of the membranous septum,[13] anomalous muscle bundles, or papillary muscles or chordae) may become more obstructive after surgical repair of ostium primum defect due to mechanisms 1 to 4 just listed.

Why, then, are LV outflow tract gradients not noted more frequently at postoperative cardiac catheterization after ostium primum ASD repair? First, mild outflow tract stenoses responsible for postoperative apical ejection murmurs may clinically be attributed to residual mitral regurgitation,[14] and cardiac catheterization may not be recommended. Second, hypoplasia of the outflow tract is generally less severe in partial than in complete atrioventricular septal defect;[11] thus, critical hemodynamic narrowing is uncommon. Third, increasing the cardiac output by exercise or isoproterenol might produce pressure gradients in patients with less critical LV outflow narrowing who have no resting pressure gradient.

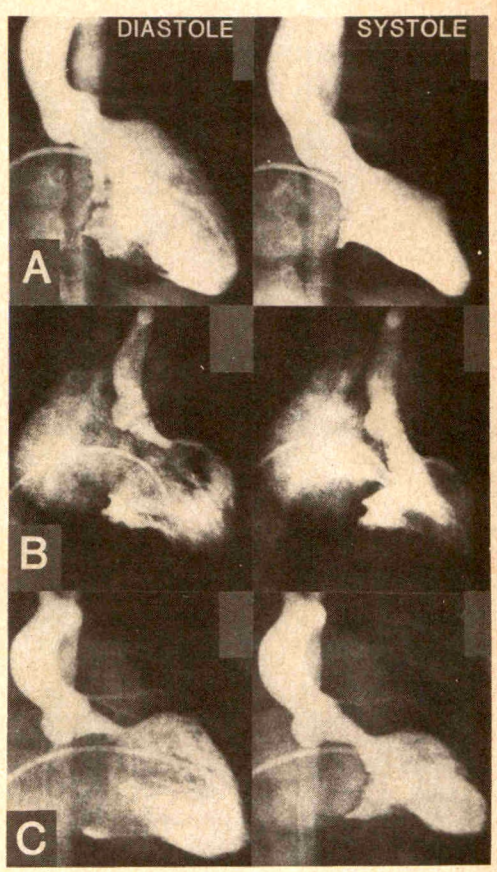

FIGURE 5. Angiographic variants of left ventricular outflow tract anatomy in ostium primum defect. **A,** rare "benign" form with no goose-neck deformity in either diastole or systole. **B,** common form with goose-neck deformity in diastole only. **C,** rare potentially obstructed form with goose-neck narrowing in both diastole and systole.

The foregoing observations indicate that surgical methods to eliminate or reduce LV outflow tract narrowing in these patients cannot be uniform. Nevertheless, hypoplasia of the subaortic area is common to most atrioventricular canal defects and removal of the discrete components alone may not always solve the problem completely or permanently. In our 3 reoperated patients, removal of a cube of septal myocardium to enlarge the outflow tunnel was performed in addition to resection of a discrete ridge stenosis, when present. However, when hypoplasia is too severe, the outflow tract may have to be enlarged more extensively to eliminate the obstruction. This can be accomplished by disconnecting the superior portion of the anterior mitral leaflet from its fusion with the ventricular septum, retracting it toward the left atrium and bridging the created gap with pericardium or other suitable synthetic material.

Because the anatomy of the LV outflow tract in ostium primum defect is not readily apparent during surgical approach aimed simply at closing the ASD and repairing the cleft of the mitral valve, patients at risk of manifesting SAS postoperatively must be identified before surgery by angiography and echocardiography. Even in the absence of surgically significant outflow pressure gradients, the presence of the characteristic systolic goose-neck narrowing preoperatively should alert the cardiologist to recommend surgical exploration of the LV outflow tract as part of the primary operative procedure or, at the least, insist on pressure measurements in the aorta and the left ventricle at the conclusion of ostium primum defect repair.

Mechanisms of Closure of Perimembranous Ventricular Septal Defect

ROBERT H. ANDERSON, MD, CORA C. LENOX, MD, and JAMES R. ZUBERBUHLER, MD

Although more defects in the muscular ventricular septum close spontaneously than do defects abutting on the membranous septum (perimembranous defects), a good proportion of the latter show a tendency to diminish in size and to close. The mechanism responsible for this closure is usually described as an aneurysm of the membranous septum, although some doubt has been cast as to whether this is the precise mechanism. In this study, 69 unoperated hearts with ventricular septal defect were examined; 26 (38%) showed some evidence of partial closure and none extended exclusively into the outlet part of the septum. Two thirds of the trabecular perimembranous defects, almost half of the inlet defects, and one third of the confluent defects showed signs of partial occlusion. The anatomic structures most frequently responsible were reduplication of tricuspid valve tissue (16 cases), adhesion of tricuspid valve leaflets (6 cases), and prolapse of an aortic valve leaflet (3 cases). Only in 2 cases were subaortic tissue tags observed which might have originated from the remnant of the membranous septum. The present study shows that although anatomic evidence of partial closure was present in two fifths of the hearts studied, only rarely was it due to so-called aneurysm of the membranous septum.

It is now well accepted that a good proportion of defects in the ventricular septum occurring in otherwise normal hearts close spontaneously or at least diminish in size sufficiently that they do not constitute a threat to the patient. Hoffman[1–3] has estimated that 40% of defects present at birth will close during the first 2 years of life and that three fifths will close by age 5 years. Small defects are more likely to close than large ones. It also has been suggested that defects in the membranous septum are less likely to close than are those elsewhere in the septum.[4] Defects abutting on the membranous septum also diminish in size or close by formation of an "aneurysm of the membranous septum."[5–7] In the last of these studies, Freedom et al[7] acknowledged that in many cases, if not most, the tissue closing the defect was not derived from the membranous septum, but rather from tricuspid valve leaflets. This finding was also shown by the well-illustrated study of Chesler et al.[8] Because of the wide acceptance of the term *aneurysm of the membranous septum* and the failure to differentiate alternate mechanisms by angiocardiographic investigation, Freedom et al[7] continued to use the term, although they compromised by adding "so-called" to their title. It now seems that cross-sectional echocardiography will provide the tool for distinction of these various mechanisms which may reduce the size of a perimembranous ventricular septal defect (VSD). Therefore, it becomes necessary to know more precisely the morphologic characteristics and origin of the structures that produce the diminution in size. With this in mind, we examined the unoperated hearts with isolated VSD in the Museum of Children's Hospital of Pittsburgh.

Material and Methods

All otherwise normal hearts having VSD were examined. Hearts with muscular or doubly committed subarterial defects with muscular posteroinferior rims were excluded. There remained 69 hearts having an isolated VSD in which the part of the central fibrous body formed by fibrous continuity between the tricuspid and aortic valves (the atrioventricular component of the membranous septum) constituted a border of the defect. Such defects are usually referred to as "membranous" VSDs. However, because the membranous septum may actually be present in such hearts and because there is

TABLE I Closure of Perimembranous Ventricular Septal Defect: Mechanism of Closure

Type of Defect	n	Nil	TV Leaflet	TV Tags	Subaortic Tags	Prolapse	Percent With Closure
Inlet	17	9	2	5	1	0	47
Trabecular	23	8	3	10	1	1	65
Outlet	20	20	0	0	0	0	0
Confluent	9	6	1	1*	0	2	33
Total	69	43	6	16	2	3	38

* One defect had both tags and prolapse.
TV = tricuspid valve.

almost always a defect in the muscular septum adjacent to the membranous septum, "perimembranous" seems a more precise term. These perimembranous defects were then examined to determine the direction of their extension into the muscular septum. On this basis, the defects were divided into inlet, trabecular or outlet types, depending on whether the defect occupied predominately the parts of the inlet, trabecular, or outlet muscular septum adjacent to the central fibrous body.[9]

Some defects were considered to extend into all 3 parts of the muscular septum, and these were designated "confluent" defects. All defects were then examined from the right ventricular aspect to see if their size was diminished by any anatomic structures. In each case the left ventricular aspect was examined to determine if there was any remnant of the interventricular component of the membranous septum present, and if this contributed to closure.

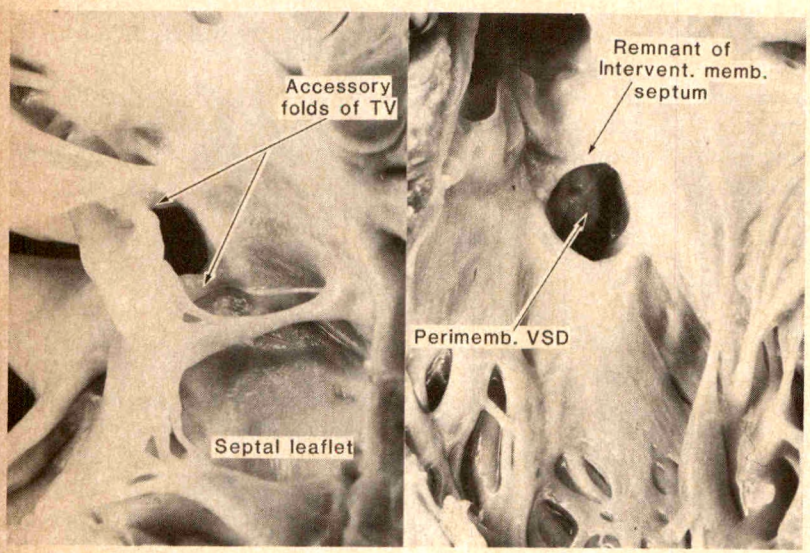

FIGURE 1. Left, the right ventricular aspect of a small perimembranous trabecular ventricular septal defect (VSD) in which the size is reduced by membranes derived from the tricuspid leaflet tissue. **Right,** the left ventricular aspect shows that the membranes are distinct from the remnant of the interventricular component of the membranous septum. TV = tricuspid valve.

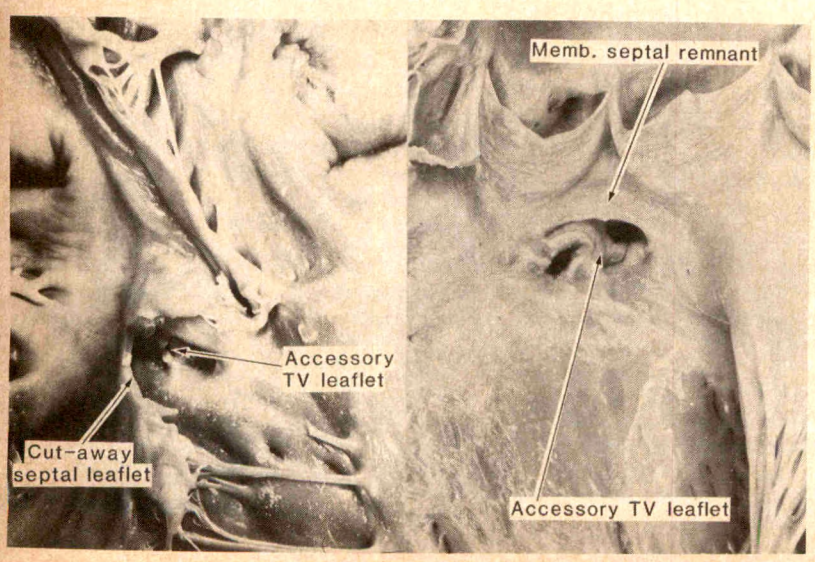

FIGURE 2. A large perimembranous septal defect almost closed by membranes, similar to those shown in Figure 1. **Right,** the left ventricular aspect again shows the remnant of the interventricular membranous septum. The folds are also discrete from the septal leaflet of the tricuspid valve (TV), which has been cut away in the **left panel.**

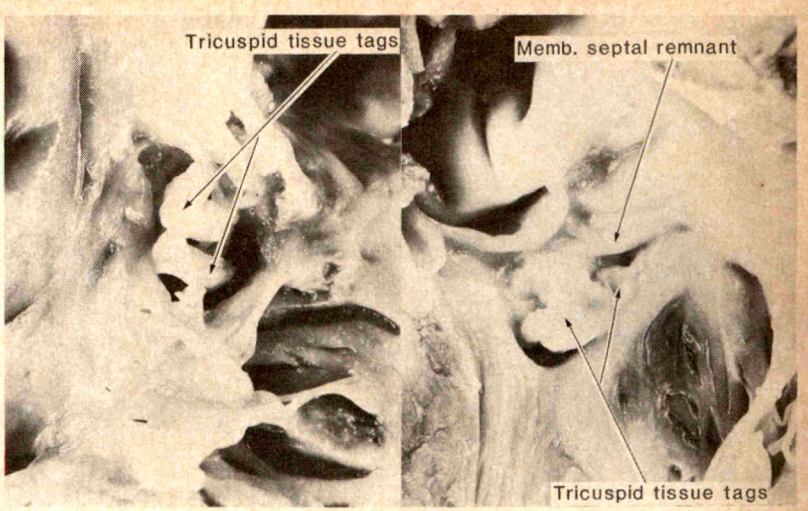

FIGURE 3. A perimembranous trabecular defect which is partially closed by grape-like tags derived from the tricuspid valve leaflets. The right ventricular (**left panel**) and left ventricular (**right panel**) aspects are shown.

Results

Of the 69 hearts examined, 26 (38%) showed anatomic evidence of diminution in size of the defect. Only 2 were completely closed, both of these by adherence of the septal leaflet of the tricuspid valve to the margin of a trabecular defect. In 24 hearts there was partial closure.

Seventeen of the 69 defects were of the inlet type and nearly half of these were partially closed. Twenty-three hearts had perimembranous defects largely confined to the trabecular septum, and two thirds of these were diminished in size. Twenty defects extended into the outlet septum and none of these showed evidence of closure. The remaining 9 hearts had confluent defects, and one third were reduced in size by discrete anatomic lesions.

The structures producing closure are listed in Table I. The majority were derived from reduplications of tricuspid valve leaflet tissue. In some cases these reduplications simply produced folds in the posterosuperior and posteroinferior quadrants of the defect (Fig. 1). These folds were discrete from the interventricular component of the membranous septum and in 3 cases produced almost complete closure (Fig. 2). In other hearts the reduplications were dysplastic and pouch-like and significantly diminished the size of the defect (Fig. 3). Sometimes the pouches were tethered by chordae tendineae both to the septal crest and to the tricuspid valve leaflets. All of these pouches were separate from the remnant of the interventricular membranous septum.

The second most common arrangement was attachment of leaflets of the tricuspid valve across the defect. In 2 hearts this arrangement produced complete closure and in another virtually complete closure of the defect (Fig. 4). In 1 heart with a confluent defect the partial closure produced by a dysplastic tricuspid valve leaflet was enhanced by prolapse of the noncoronary and right coronary leaflets of the aortic valve (Fig. 5). Prolapsed aortic valve leaflets reduced the size of the defect in 2 other hearts with trabecular and confluent defects, respectively.

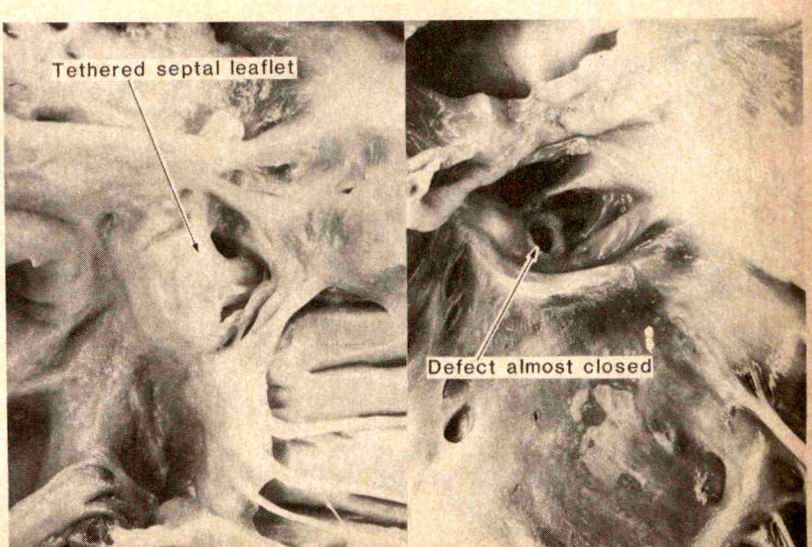

FIGURE 4. The right ventricular (**left panel**) and left ventricular (**right panel**) aspects of a perimembranous trabecular defect almost closed by adhesion of the septal leaflet of the tricuspid valve.

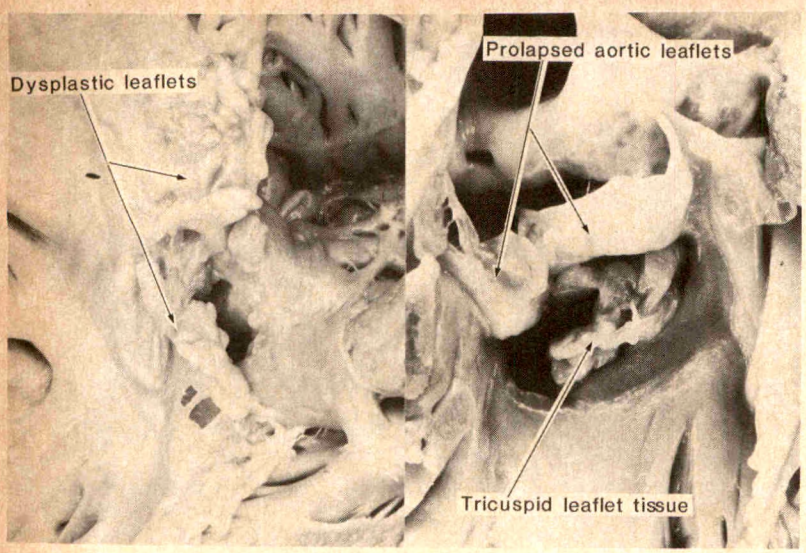

FIGURE 5. A perimembranous trabecular defect in which size is diminished in part by dysplastic conversion of the tricuspid valve leaflet (**left panel**) and in part by prolapse of the right and noncoronary aortic valve leaflets (**right panel**).

Lesions that may have originated from the interventricular component of the membranous septum were found in only 2 hearts, 1 with an inlet and the other with a trabecular defect. In 1 of these a grape-like expansion of fibrous tissue originated from the aortic root beneath the left coronary aortic valve leaflet and was tethered to the septum by chordae. A small protuberant and thickened membranous septal remnant hung in the roof of the defect medial to this structure. The predominant effect of these lesions was to produce subaortic outflow tract obstruction (Fig. 6), but there was narrowing of the VSD as well. In the second heart a long-sac like structure in the anticipated site of the interventricular membranous septum was attached by long chordae to the muscular septum, and both reduced the size of the VSD and produced subaortic obstruction (Fig. 7).

Discussion

Although Varghese et al[5,6] promoted "aneurysm of the membranous septum" as a mechanism for closure of perimembranous VSD, the larger study by Freedom et al[7] from the same institution showed that it was unlikely that the closing tissue was derived from the interventricular component of the membranous septum or its remnant. This conclusion had already been reached by Chesler et al[8] from observations on a small series of hearts. Examination of our larger series of hearts simply serves to confirm these observations. In most cases the tissue partially or completely occluding the defect is either a tricuspid valve leaflet itself or extrusion of folds of tissue from the ventricular aspect of the valve leaflets in the environs of the defect. These folds are closely related to the interventricular compo-

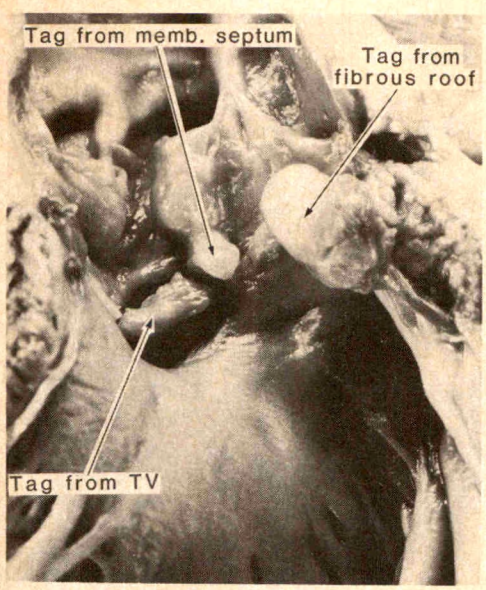

FIGURE 6. A heart with a small perimembranous trabecular defect with 3 subaortic tissue tags derived from the tricuspid valve leaflet (TV), the remnant of the interventricular membranous septum and the subaortic fibrous root. Note that the membranous remnant tag is the smallest of the 3.

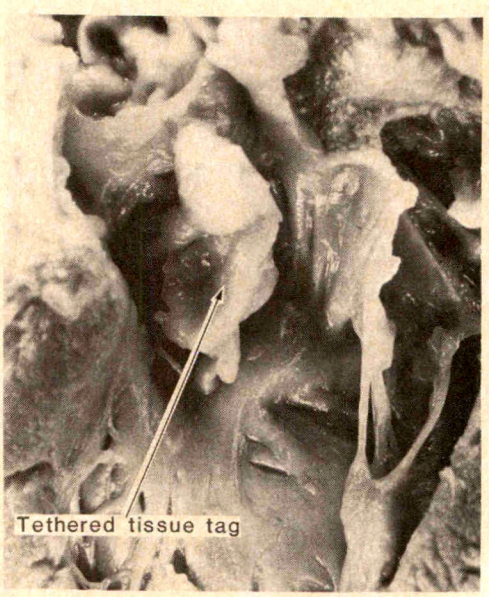

FIGURE 7. Another heart with a perimembranous defect partially blocked by an extensive sac-like aneurysm which originates from the site of the remnant of the interventricular membranous septum. The tissue tag considerably narrows the left ventricular outflow tract.

nent of the membranous septum when the latter structure is present, but they are discrete from it. In 2 hearts grape-like lesions originated from a remnant of the membranous septum and obstructed the subaortic outflow tract as well as narrowed the VSD. It may be significant that in other situations in which such fibrous tissue tags are found originating from membranous septal remnants, they too produce outflow tract obstruction rather than closure of a VSD. Examples are the tissue tags found in complete[10] and corrected[11] transposition and in atrioventricular septal defects ("endocardial cushion defects").[12,13] Although these tags are often said to be derived from endocardial cushion tissue,[7,12] we know of no work, experimental or otherwise, to substantiate this statement. We cannot be sure that these lesions originated from the membranous septum, but we cannot identify any other tissue as their source. It is probably most accurate to describe them simply as subaortic tissue tags.

In 3 cases prolapsed aortic valve leaflets reduced the defect size, a mechanism described by Moss and Siassi.[14] We also encountered a case clinically in which a VSD murmur disappeared synchronously with the appearance of a murmur of aortic regurgitation.

When Freedom et al[7] discussed their use of the term *aneurysm of the membranous septum*, they justified it by common usage, inability to distinguish the anatomy in a clinical setting, and lack of a superior term. We would suggest that cross-sectional echocardiography now provides the means of distinguishing the different lesions which diminish the size of perimembranous VSDs. Simple descriptive terms account for their categorization. Thus, in our series diminution in size was produced either by an adherent tricuspid valve leaflet, tricuspid leaflet tissue tags, subaortic tissue tags, prolapsed aortic valve leaflets, or a combination of these. Our study also showed that nearly two fifths of perimembranous VSDs had some signs of closure. These figures must be treated with caution because they are obtained from an autopsy series. We obviously cannot be sure that the partial occlusion demonstrated in these hearts was part of a dynamic process which would have led to complete closure had the child survived long enough. However, the fact that none of the outlet perimembranous defects showed signs of closure is surely significant, substantiating Somerville's concept[15] that the position of a perimembranous defect within the septum is just as important in its natural history as the fact that it is subaortic and abuts directly on the central fibrous body.

2-Dimensional Echocardiographic Appearance of Complete Left-Sided Juxtaposition of the Atrial Appendages

ALVIN J. CHIN, MD, FREDRICK Z. BIERMAN, MD, ROBERTA G. WILLIAMS, MD, STEPHEN P. SANDERS, MD, and PETER LANG, MD

This report describes the 2-dimensional (2-D) echocardiographic appearance of left-sided juxtaposition of the atrial appendages (JAA). From January 1, 1978, to June 30, 1979, 2 infants had the diagnosis of left-sided JAA at autopsy. Both patients had previously been examined by subxiphoid 2-D echocardiography. On review of these studies, the septum secundum was found to be oriented posteriorly in the transverse view of the atria. From July 1979 to June 1981, prospective evaluation of all infants for the presence of this finding revealed 2 more patients. Left-sided JAA was confirmed at surgery in 1 case and by selective right atrial angiography in the other. The diagnosis of left-sided JAA has important implications for both atrial baffle operations and for the Fontan procedure.

Left-sided juxtaposition of the atrial appendages (JAA) is an unusual anomaly typically associated with several types of conotruncal malformations: d-transposition of the great arteries, some varieties of double-outlet right ventricle, and anatomically corrected malposition.[1–5] It may occur in complete or partial form[2,6,7] and frequently coexists with hypoplasia of the tricuspid valve and right ventricular sinus. It is particularly increased in frequency among patients with the {S,D,L} segmental combination.[8] Several reports have described the angiographic diagnosis of JAA.[9–11] This report presents the 2-dimensional (2-D) echocardiographic appearance of left-sided JAA and discusses the surgical implications of this diagnosis.

Methods

From January 1, 1978 to June 30, 1979, the diagnosis of left-sided JAA was made at autopsy in 2 infants. Both had been examined by 2-D echocardiography at the Children's Hospital Medical Center, Boston. From July 1, 1979 to June 30, 1981, all patients <2 years old who were examined by 2-D echocardiography were prospectively evaluated for left-sided JAA. All 2-D echocardiographic examinations were performed from the subxiphoid region with a Picker Echoview 80 CI system, using either a 5-MHz short-focus (active element diameter 13 mm) or 3.5-MHz medium-focus (active element diameter 13 mm) crystal. The transverse echocardiographic plane used is shown in Figure 1.

Results

In the retrospective examination of the 2-D echocardiograms of the first 2 patients, the atrial appendages themselves were convincingly exhibited in only 1 patient. However, we discovered 1 unusual finding common to both cases: in the transverse view of the atria, the septum secundum was deviated posteriorly (Fig. 2A). The orientation of the septum primum in these 2 patients was normal. From July 1979 to June 1981, prospective examination of all infants for the presence of an abnormally posteriorly deviated septum secundum revealed 2 further patients with this feature. Left-sided JAA was subsequently confirmed at surgery in 1 and by selective right atrial angiography in the other. The true incidence of false-negative diagnosis based on the orientation of the septum secundum is unknown, since a significant number of infants undergoing 2-D echocardiography never undergo further investigation. However, of the 480 infants during the study with a normally oriented septum secundum who did have subsequent cardiac catheterization, surgery, or autopsy, none was diagnosed as having left-sided JAA.

Discussion

Although several investigators have described the angiographic diagnosis of JAA;[10,11] there have not been

any reports of the 2-D echocardiographic appearance of this anomaly. The atrial appendages themselves are often difficult to display because of their tortuosity and their apposition to the lungs. Although the left atrial appendage can be imaged in some patients, the right atrial appendage is especially difficult to identify consistently, and it is the right atrial appendage which is displaced in left-sided JAA. However, the qualitative assessment of septum secundum orientation in the transverse view of the atria appears to be a reliable test for the presence of left-sided JAA.

Examination of both autopsy cases revealed that the septum secundum was deviated posteriorly and leftward, as was its external counterpart, the superior-most aspect of the interatrial fold (Fig. 3). It is thus not surprising that the transverse view of the atria (Fig. 1) shows this deviation so clearly.

Two thirds of reported cases with left-sided JAA have d-transposition of the great arteries[1–7,9–12] and would be expected to undergo balloon atrial septostomy. In patients with left-sided JAA, the septostomy catheter may appear by fluoroscopy to be in the left atrium when it is, in fact, in the levo-posed right atrial appendage.[10,12] Inflating the balloon of the septostomy catheter in the right atrial appendage and pull back could result in eversion of the appendage or rupture of the right atrium. Precatheterization knowledge of the presence of JAA alerts the cardiologists to this potential hazard; 2-D echocardiography can also be used to confirm catheter position before performing balloon septostomy.[13]

The presence of left-sided JAA may alter surgical management of certain associated lesions. First, in cases of double-outlet right ventricle or d-transposition of the great arteries where there is atresia or hypoplasia of the tricuspid valve, physiologic surgical repair may involve a right atrial–pulmonary artery conduit or direct anastomosis. In patients with d-malposed great vessels, left-sided JAA places the levo-posed right atrial appendage adjacent to the main pulmonary artery. Awareness of the presence of left-sided JAA alerts the surgeon to the technical feasibility of fashioning a patulous side-to-side anastomosis between the right atrial appendage and the main pulmonary artery. In the face of early reports of conduit obstruction after the Fontan procedure,[14,15] a direct right atrial–pulmonary artery anastomosis, rendering an artificial conduit unnecessary, appears to be an increasingly attractive

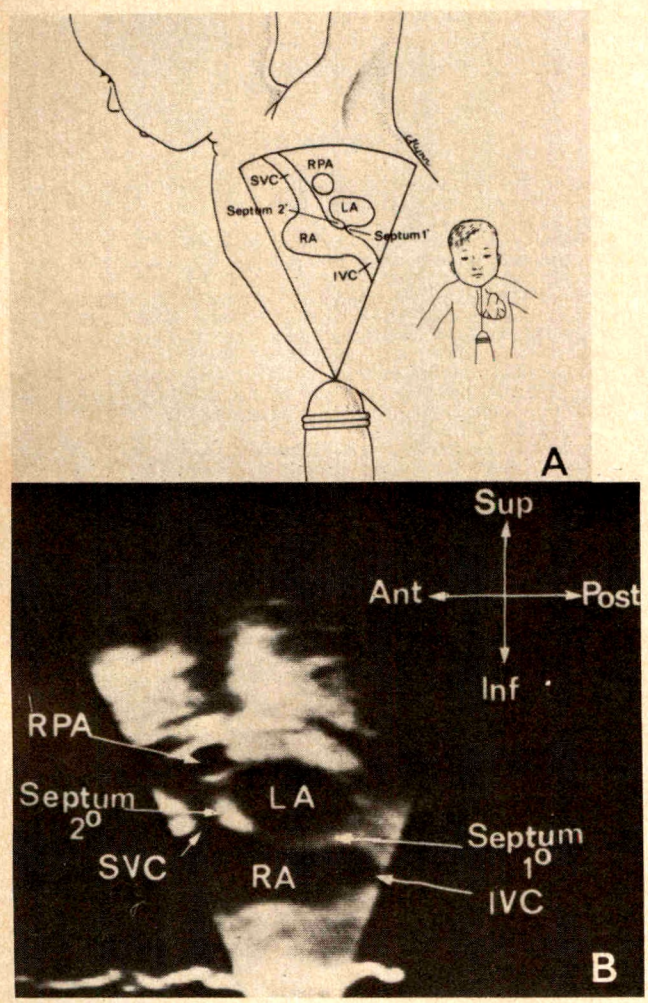

FIGURE 1. A, ultrasound plane used to obtain the transverse view of the atria. FIGURE 2. A, 2-dimensional echocardiogram of patient with complete left-sided justaposition of the atrial appendages, transverse view of the atria. The septum secundum (2°) is deviated posteriorly. An atrial septal defect is present. **Open circles** outline the anterior margin of the superior vena cava. **B,** 2-dimensional echocardiogram of a patient with a secundum atrial septal defect but without juxtaposition of the atrial appendage transverse view of the atria. Note the absence of any posterior deviation of the septum secundum (**white arrowhead**). Abbreviations as in Figure 1.

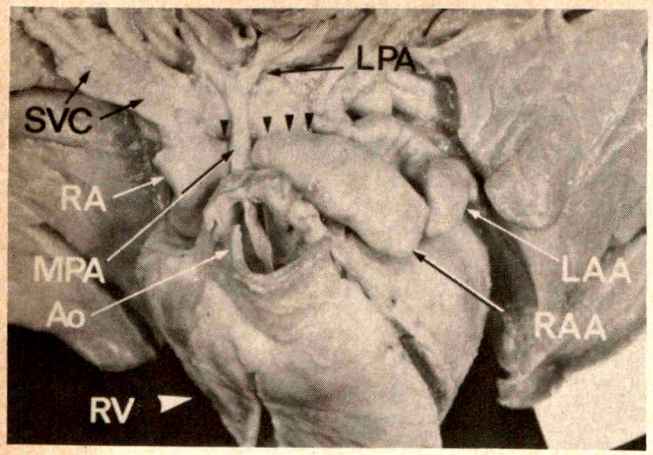

FIGURE 3. Autopsy specimen (external superior view) of the patient whose echocardiogram is shown in Figure 2A. The external counterpart of the septum secundum, the interatrial fold (**black arrowheads**), is deviated leftward and posteriorly in complete left-sided juxtaposition of the atrial appendages. This patient had double-outlet right ventricle with pulmonary atresia, atrioventricular canal–type ventricular septal defect, secundum atrial septal defect, and large patent ductus arteriosus. The right atrial appendage (RAA) is levo-posed through the transverse sinus posterior to the great arteries. Ao = aorta; LAA = left atrial appendage; LPA = left pulmonary artery; MPA = main pulmonary artery; RA = right atrium; RV = right ventricle; SVC = superior vena cava.

surgical technique. Second, the Blalock-Hanlon procedure appears to be technically more demanding in patients with left-sided JAA. Rosenquist et al[7] noted that the part of the right atrium between the interatrial groove and the atrioventricular sulcus is smaller than normal, making the placement of a vascular clamp hazardous. Open atrial septectomy may be the safer technique in patients with left-sided JAA. Third, atrial baffle operations such as the Mustard and Senning procedures pose special problems in patients with left-sided JAA. Just as for the Blalock-Hanlon procedure, the major complicating feature appears to be the "small right atrial cavity size."[16] We believe that the right atrium appears small in complete left-sided JAA because the only portions of the right atrium between the interatrial groove and the right atrioventricular sulcus are the sinus venosus component and the small portion contributed by the right half of the atrioventricular canal. The primitive atrium component including the right atrial appendage is levo-posed through the transverse sinus posterior to the great arteries (Fig. 3). To deal with the small right atrium in Mustard repair, Urban et al[16] suggested extending the right atriotomy incision across the interatrial groove between the right upper and lower pulmonary veins and inserting a Dacron® patch to enlarge the pulmonary venous atrium (neo–left atrium). Although so far only Mustard repairs[16,17] have been reported in patients with left-sided JAA, we anticipate that an analogous enlargement of the neo–left atrium during the Senning repair would also be required.

Two-dimensional echocardiography affords an opportunity to examine the in vivo spatial relations of cardiac structures and can frequently offer new insight regarding the possible embryologic basis of complex cardiac anomalies. The posterior displacement of the septum secundum together with the posterior and leftward displacement of the right atrial appendage suggested a possible explanation of the morphogenesis of this condition. It is possible in this lesion that during embryogenesis the primitive atrium, whose only derivatives are the septum secundum and the atrial appendages, becomes malaligned with respect to the sinus venosus. The possibility of malalignment of cardiac segments with respect to one another may explain many cardiac anomalies[18]; for example, there is a spectrum of alignment of the common atrioventricular valve vis-a-vis the ventricles in complete common atrioventricular canal.[19] Similarly, the degree of malalignment between the primitive atrium and the sinus venosus may thus determine whether there is partial or complete juxtaposition of the atrial appendages. Finally, the theory that abnormal septum secundum orientation is associated with JAA predicts that the septum secundum should be deviated rightward and anteriorly in right-sided JAA.

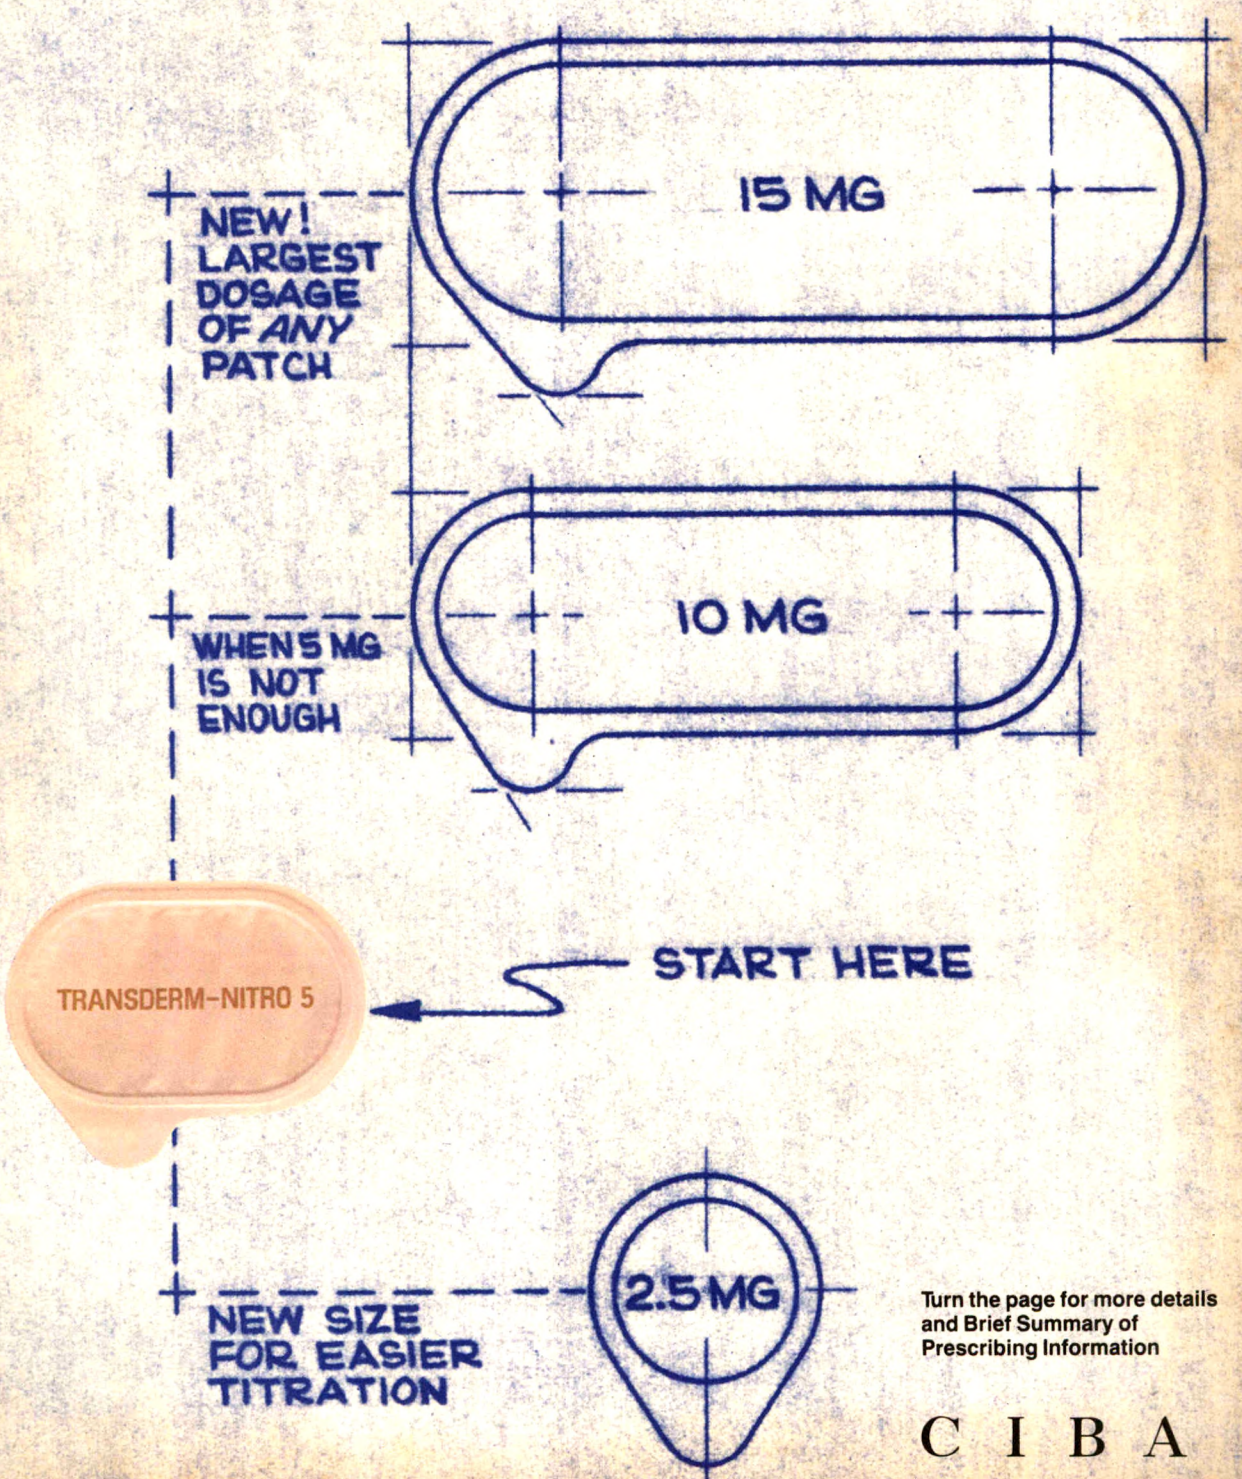
Now...custom-built anginal therapy

Transderm®-Nitro

nitroglycerin

More sizes...more flexibility...
more precise titration



Turn the page for more details and Brief Summary of Prescribing Information

CIBA

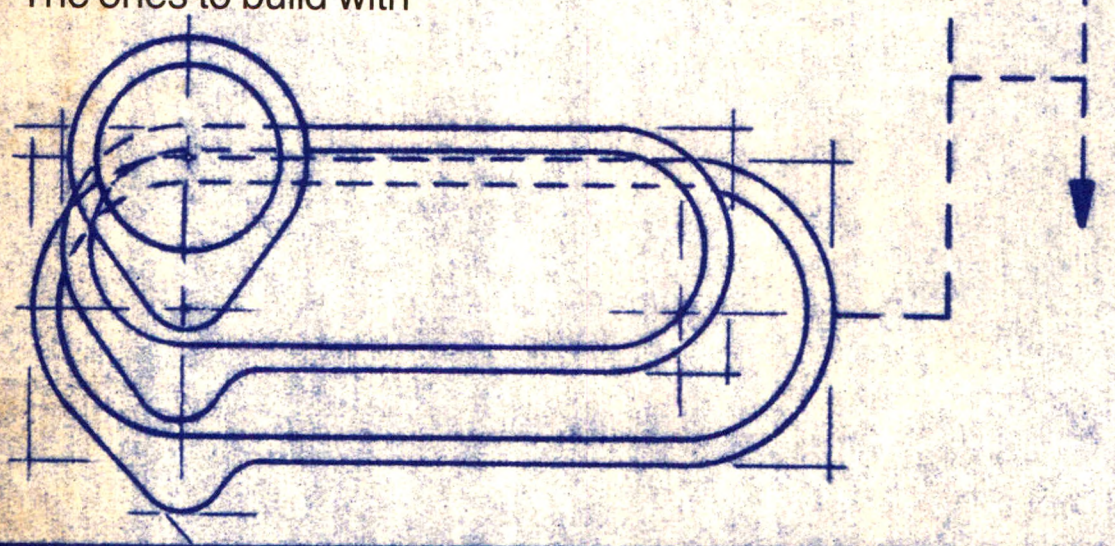
Transderm®-Nitro
nitroglycerin

New dosage versatility—more useful than ever

The complete line: 2.5 mg, 5 mg, 10 mg, 15 mg

The one to build on

The ones to build with



- consistent 24-hour anginal control with one, simple 10-second application
- small, convenient, easy to use
- dosage strength is clearly marked on the front for easy identification

Side effects include transient headaches and orthostatic hypotension. Contraindicated in patients with increased intraocular pressure. Withdrawal from treatment should be gradual.

Consult complete product information before prescribing.

CIBA

First with the future in drug delivery systems

Transderm®-Nitro (nitroglycerin) **Transdermal Therapeutic System**
Brief Summary of Prescribing Information

INDICATIONS AND USAGE
Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

Growth and Tissue Abnormalities in Young People With Cyanotic Congenital Heart Disease Receiving Systemic–Pulmonary Artery Shunts

DAVID BAUM, MD, REBECCA Q. BECK, MA, and WILLIAM L. HASKELL, PhD

The effects of systemic–pulmonary artery shunts on growth, body composition, and adipose tissue were studied in 29 children, aged 2 to 16 years, with cyanotic congenital heart disease. Of these, 16 received surgical shunts and 13 were unoperated. Postoperatively, all patients who received shunts were better oxygenated (systemic oxygen saturation 69 ± 11% preoperatively and 84 ± 4% postoperatively; mean ± standard error of the mean) and were symptomatically improved. However, the groups were not significantly different in height, weight, lean body mass, total body fat, lean/fat ratio, cellular lipid content, or total number of lipid-containing fat cells. Age at operation did not seem to influence the effects of surgery. These observations suggest that growth and certain measurements of tissue development were unaffected by surgical systemic–pulmonary artery shunts despite increased oxygenation and symptomatic improvement after operation.

Young persons with cyanotic congenital heart disease are short and underweight.[1–3] They have reduced lean and fat tissues. The reduction in adipose tissue seems largely the result of a subnormal number of lipid-containing fat cells rather than diminished cellular lipid content.[1] While there is general agreement that height and weight are reduced in cyanotic patients with reduced pulmonary blood flow, there is less agreement concerning the rate of growth and weight gain after systemic–pulmonary artery shunts.[1,3–6] Regardless of whether growth and weight gain are accelerated after palliation, patients remain undersized and underweight despite improvement in oxygenation.[1,3–6] The tissue abnormalities that contribute to these disorders in surgically shunted cyanotic children are unknown. This study was performed to determine the fat and lean tissue changes associated with poor growth and weight gain in such patients.

Methods

Children aged 2 to 16 years at the time of cardiac catheterization were studied. All had cyanotic congenital heart disease and reduced pulmonary blood flow. Patients born prematurely or with metabolic disease, chromosomal aberrations, or other significant noncardiac congenital defects were excluded.

Thirteen unoperated patients (5 girls, 8 boys) comprised 1 group. The second group included 16 young persons (3 girls, 13 boys) who received palliative surgery consisting of a Blalock-Taussig (n = 11), Potts (n = 2), or Waterston (n = 3) anastomosis. Although height, weight, and adipose and lean tissue mass were determined longitudinally, tissue studies were performed only at the time of cardiac catheterization. In patients 2 to 14 years of age, lean and fat tissue mass were derived by the Friis-Hansen method.[7] Hydrostatic weighing[8] was used for those >14 years of age. For cellular studies, small adipose samples were obtained through the groin incision made for percutaneous catheter introduction. Fat cell size (cellular lipid content) and total number of lipid-containing adipocytes were determined.[9] When available, height and weight of the parents also were recorded.

Group comparisons of height, weight, lean body mass, total body fat, lean/fat ratio, cellular lipid content, and total number of lipid-containing adipocytes were performed using the analysis of variance (BMD computer program). A Student *t* test was used to determine the significance of the difference between 2 means. P values <0.05 were considered significant.

Results

Patients: The most common cardiac anomaly in both groups was tetralogy of Fallot (20 of 29 patients). Six had complex cyanotic heart disease, 2 double-outlet right ventricle and pulmonary stenosis, and 1 transpo-

sition, ventricular defect, and pulmonary stenosis. All children were cyanotic in the first year of life. Oxygen saturation in the nonoperated patients was 77.7 ± 6.0% (mean ± standard error of the mean [SEM]).

Surgical decisions were based upon symptoms, degree of hypoxemia, complexity of cardiac anomalies, size, and age. In patients who received palliative surgery, preoperative oxygen saturation was 68.8 ± 11.2% and postoperative saturation was 83.6 ± 4.0%. All children who received a shunt had improvement in symptoms. Age at operation was 3.2 ± 3.5 years (range 0.01 to 9.4). Seven of the 16 palliated patients were operated upon before age 0.7 years, with 4 in the first month of life. Of those operated upon very early, arterial oxygen saturation increased from 63.7 ± 12.8% to 82.7 ± 3.5%.

Height and weight: Comparison of the 2 groups of patients revealed no difference in height or weight. When these data were expressed as the percentiles of the general American population,[10] height and weight of the 2 groups again were not significantly different. In the group receiving surgery, there were no significant differences in pre- and postoperative height and weight percentiles. Furthermore, in operated patients in whom sufficient data were available, there was no apparent difference in the pre- and postoperative rates of growth and weight gain. At the time of cardiac catheterization, the patients' height and weight, expressed as percentiles, were compared with those of their parents.[11] Unoperated children were shorter ($p < 0.01$) than their mothers and both shorter ($p < 0.01$) and lighter ($p < 0.025$) than their fathers. Palliated patients were lighter ($p < 0.025$) than their mothers but both shorter ($p < 0.01$) and lighter ($p < 0.01$) than their fathers.

Tissue analyses: Lean and adipose tissue mass in the shunted group was not significantly different from those of the nonshunted group (Fig. 1 and 2). In those operated patients with sufficient pre- and postoperative data to allow comparison, palliative surgery produced no difference. To learn whether palliative surgery produced a proportional change in body composition, lean/fat ratios in the 2 cyanotic groups were compared. Since there was no significant difference in the ratios (Fig. 3), it appeared that palliation did not alter the fat and lean tissue contributions to the hypoxemia-induced decrease in body weight.

Neither cellular lipid content (Fig. 4) nor number of lipid-containing fat cells (Fig. 5) was significantly different in operated and nonoperated patients.

Discussion

Despite improved oxygenation and symptomatic relief, our patients' growth and weight gain were not improved after systemic–pulmonary artery shunts. Similarly, the relative contributions of fat and lean tissue components to their underweight were not af-

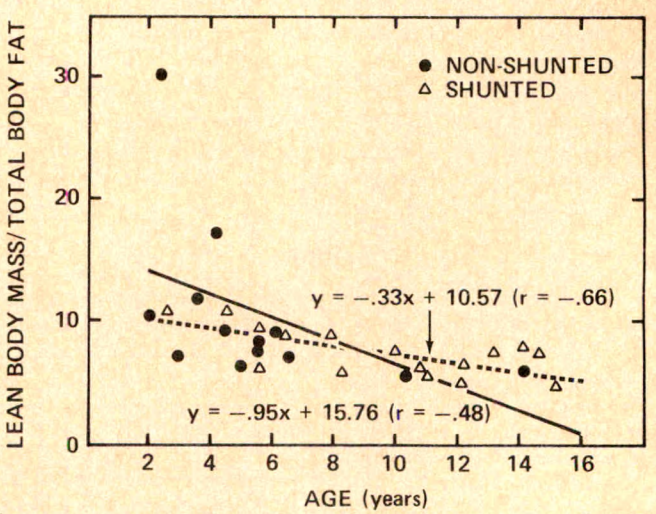

FIGURE 3. Lean/fat ratio in shunted and nonshunted children with cyanotic congenital heart disease. Regression lines and correlation coefficients are shown.

fected. These conclusions were made because height, weight, lean and fat tissues, and lean/fat ratios in unoperated and postoperative patients given palliative shunts were not significantly different. Further supporting this conclusion, the rates of growth, weight gain, and lean and fat tissue change seemed no different before and after operation. Although preoperative arterial oxygen saturations in operated children were lower than arterial oxygen saturations in nonoperated children, we believe that our comparisons were valid for 2 reasons. First, there was a subgroup of shunted children with only a very brief period of severe hypoxemia. In this subgroup, 7 palliated infants were operated upon before age 0.7 year, with 4 in the first month of life. Yet there were no growth differences between children operated upon before 0.7 year and those shunted later. Neither differed from nonoperated patients. Second, postoperative arterial oxygen saturations were greater than oxygen saturations of nonshunted patients. As a result, over the course of their illness, hypoxemia was less of a handicap to operated than unoperated children.

There are several reasons why growth and weight gain may not improve postoperatively. Although oxygenation is increased, it is still subnormal. The original congenital heart disease remains and, in fact, palliative surgery imposes an additional left-to-right shunt. Thus, cardiopulmonary work remains abnormally high.[12] As long as the children continue to be underweight, the ratio of surface area to body weight is high and, as a result, heat loss is facilitated.[13] Finally, palliated children often continue to eat poorly and there is reason to believe that gastrointestinal absorption may be impaired.[14] Therefore, substrate needs, including that of oxygen, are greater than normal, while substrate availability is decreased. This combination of circumstances results in less residual substrate for storage and growth.

Children with successful palliative shunts often benefit from the surgery. With increased pulmonary blood flow, oxygenation is improved and polycythemia decreased. Activity is increased, symptoms are relieved, and hypoxic spells may cease. Nevertheless, growth failure continues. Reduction in weight, adipose tissue mass, and number of lipid-laden cells and decreased height and lean tissue suggest a widespread structural abnormality. Since structural abnormality is often associated with functional disorders, the described tissue abnormalities in cyanotic patients may portend disordered cellular function.

Structural and functional derangements of adipose tissue as well as secondary changes involving other organs may be important.[15,16] Such tissue changes may reach a stage when they become irreversible. While there is evidence suggesting that adipose tissue abnormalities produced in young animals are not fully reversible,[17,18] whether such irreversibility occurs in man is not known. Undoubtedly, factors such as symptoms, age, and size still remain the primary considerations in the surgical decision. However, if there is a stage in the young developing child when hypoxemia-induced tissue defects become irreversible, the limited growth benefits of palliative shunting deserve attention in planning long-term management.

The Marfan Syndrome in Early Childhood: Analysis of 15 Patients Diagnosed at Less Than 4 Years of Age

HENDRICA E. SISK, MD, KENNETH G. ZAHKA, MD, and
REED E. PYERITZ, MD, PhD, *With the technical assistance of* CATHY HENSLEY

The clinical, cardiac and echocardiographic features were reviewed of 15 consecutive infants and children with the Marfan syndrome who presented at <4 years of age. The 10 females and 5 males were diagnosed at a mean age of 18 months (range 2 days to 3.5 years); 13 were followed up for a mean of 45 months (range 8 to 109 months) and 2 were lost to follow-up. On first evaluation, 5 patients had mitral regurgitation (MR) and none had aortic regurgitation (AR). Echocardiography showed aortic root dilatation in 9 and mitral valve prolapse (MVP) in 9; only 2 patients had a normal echocardiogram. At follow-up examination, all patients had aortic root dilatation; the rate of increase in aortic root diameter was generally greater than predicted on the basis of body surface area. One patient had AR at age 10 years. All 13 patients had MVP; 9 had progressive mitral valve dysfunction and 4 had mitral valve replacement. One patient died immediately postoperatively. Thus, aortic root dilatation is usually present in early childhood and serves as an objective indicator of the Marfan syndrome. MVP is common and MR, which may require valve replacement, is the leading cause of cardiovascular morbidity in childhood. Echocardiography is useful in the diagnosis and routine management of infants and children in whom the Marfan syndrome is suspected.

The Marfan syndrome is a heritable disorder of connective tissue in which the most prominent abnormalities occur in the skeletal, ocular, pulmonary, and cardiovascular systems.[1–4] Skeletal features were described in 1896[5] and mitral valve dysfunction was first noted in a patient with arachnodactyly in 1912.[6] Many years later, cardiovascular features were recognized as integral to the syndrome. Aortic dilatation[7] and dissection[8] were reported in 1943 and fragmentation and disarray of elastic fibers in the aortic media were noted. This histopathology, called cystic medial necrosis, also occurs in other connective tissue disorders[9] and in association with hypertension and aging.[10] Early surveys of cardiovascular involvement in the Marfan syndrome focused on diagnosis by auscultation or postmortem examination.[11,12] Estimates of frequency of abnormalities ranged from 40 to 60% of adults in these studies.

Address for reprints: Kenneth G. Zahka, MD, Division of Pediatric Cardiology, The Johns Hopkins Hospital, Baltimore, Maryland 21205.

Appreciation of frequency and kind of cardiovascular features in patients with Marfan syndrome was greatly altered by the introduction of echocardiography. Several surveys of adults and children detected mitral valve prolapse (MVP), aortic dilatation or both in about 95%.[2,13–15] In the studies reported here, we analyzed clinical and echocardiographic findings in children <4 years of age who met strict criteria for the diagnosis of Marfan syndrome and were evaluated consecutively in 1 clinic, to determine the frequency, severity, and natural history of their cardiovascular abnormalities.

Methods

The medical records of all patients with the Marfan syndrome <4 years of age who were evaluated between 1970 and 1982 in the Medical Genetics Clinic were reviewed. Diagnosis of the Marfan syndrome was based on skeletal, ocular, and cardiovascular features and family history.[2] All subjects underwent echocardiography, but in no case were the results used in establishing the diagnosis. The study included 5 boys and 10 girls who presented at 2 days to 3½ years of age (mean 18 months). This group comprised about 9% of all patients <22 years old affected by the Marfan syndrome evaluated at our institution during the same period. Seven patients had a parent affected by the Marfan syndrome; the other 8 had a negative family history for connective tissue disorders. Examination and echocardiography of their parents did not re-

veal features of the Marfan syndrome, except for isolated MVP in 1 mother. Each child underwent detailed ophthalmologic examination. Cardiac auscultation was performed with the patient in the supine, left lateral decubitus, and upright positions. Skeletal, ocular, and family history data are summarized in Table I. Thirteen of the 15 patients were followed up for 8 to 109 months (mean 45). Two patients were lost to follow-up. No patient was taking medication when first evaluated; 2 were subsequently treated with digoxin for atrial flutter and 1 with propranolol as prophylaxis against aortic dilatation and dissection.[4,16]

Echocardiograms were performed with the patient supine using a Smith-Kline Ekoline 20A instrument with a Honeywell 1956 recorder and a 3.5 or 2.25-MHz Aerotech transducer. The transducer position was adjusted along the lower left sternal border to record the left ventricular cavity, with simultaneous visualization of the posterior wall and ventricular septum just below the mitral valve tips. Damping was adjusted to obtain clear endocardial and epicardial echoes. Aortic root and left atrial recordings were made at the level of the aortic valve leaflets. Left ventricular diastolic dimension, left ventricular systolic dimension, ventricular septal thickness, posterior wall thickness, aortic root dimension, and left atrial dimension were measured as described by Sahn et al.[17] Mitral valve prolapse was defined as deflection of a mitral leaflet posterior to the "C" point by at least 2 mm throughout systole or beginning in midsystole. Each measurement was plotted as a linear function of body surface area, with normal values defined as those falling within the 95% prediction intervals for normal children described by Henry et al.[18]

Results

The clinical cardiovascular features at the first, preoperative (where pertinent), and latest evaluations at our institution are summarized in Table II. On the first physical examination, 2 patients had an isolated, apical, nonejection systolic click, 5 had a pansystolic apical murmur consistent with mitral regurgitation (MR), and 5 had normal findings on auscultation. None had audible aortic regurgitation (AR) or clinical evidence of any congenital heart defect.

The most recent or immediate preoperative physical examination of the 13 children available for follow-up examination revealed an isolated, apical, nonejection systolic click in 6, isolated MR in 4, and MR and AR in 1. Seven patients had progression of mitral valve dysfunction, defined as appearance of a new systolic click, an increase in the murmur of MR by at least 2 grades, or appearance of congestive heart failure in the absence of AR. Four patients developed severe MR and underwent valve replacement. One of these patients died immediately after mitral valve surgery at age 11 months of left ventricular dysfunction and the other (Patient 2) had AR during follow-up.

Echocardiographic measurements standardized for body surface area were compared with each other and with data from Henry et al[18] for normal children. The most frequent abnormality at the first examination, present in 9 patients, was aortic root enlargement, which was >95% prediction intervals for normal children. Nine patients, 5 of whom had neither a systolic click nor an apical systolic murmur on auscultation, had MVP. The only other abnormality was an increased left ventricular diastolic dimension in 4 patients, 3 of whom had MR.

The echocardiograms taken from each of the 13 patients during their follow-up study were examined. All patients had an aortic root dimension at or above the normal range; the increase in aortic root diameter was greater than predicted on the basis of growth in body surface area in most cases (Fig. 1). All patients had or developed MVP. Nine had echocardiographic criteria for progression of mitral valve dysfunction, specifically, appearance of new MVP or development of left atrial or left ventricular enlargement in the absence of AR. Four patients with increased left ventricular diastolic dimensions required mitral valve replacement (Fig. 2). For most examinations, left atrial and ventricular systolic dimensions were within normal limits, and in all the echograms ventricular septal and posterior wall thicknesses were normal.

Discussion

Review of cardiac involvement in children with the Marfan syndrome: Reports of infants and young children with the Marfan syndrome have focused on severely affected patients who usually had prominent cardiovascular involvement and most were published before the availability of echocardiography.[19–29] Many patients <3 years of age had MR, but not AR; nonetheless, dilated sinuses of Valsalva were documented often on angiocardiography or at autopsy. In the largest pediatric series, 36 patients <16 years old, including 2 infants, were described; most had apical nonejection systolic clicks, MR alone or with a click, or AR as well as dilatation of the sinuses of Valsalva detected at cardiac catheterization.[27]

There are few reports of the cardiac manifestations of the Marfan syndrome in young children that include echocardiography. Brown et al[14] studied 35 patients, 14 of whom were <16 years but none <3 years. Spangler et al[13] reported on 26 patients, including 6 <16 years and 3 infants. Two infants had both AR and MR and 1 had MR and congestive heart failure; all had MVP, left atrial enlargement and aortic dilatation on echocardiography. These studies, and several studies of echocardiograms in adult patients with Marfan syndrome,[30] suggest the following: First, aortic dilatation may appear early in life. Second, aortic dilatation precedes the appearance of AR in some instances. Third, aortic dilatation may not be detectable by clinical examination or chest radiography. Finally, MVP is common and may be associated with severe MR. These cross-sectional studies, however, have provided little insight into the natural history of aortic dilatation and mitral valve dysfunction in the Marfan syndrome.

The group of patients described in this study is likely to be more representative of young patients with Marfan syndrome than any heretofore published because it is not composed solely of severely affected patients referred for management of cardiovascular, ocular or skeletal problems, but also of patients ascertained through family studies. All 7 children with a family history of the Marfan syndrome were first evaluated because of parent or physician concern about whether the child was affected and not because of a specific medical complaint.

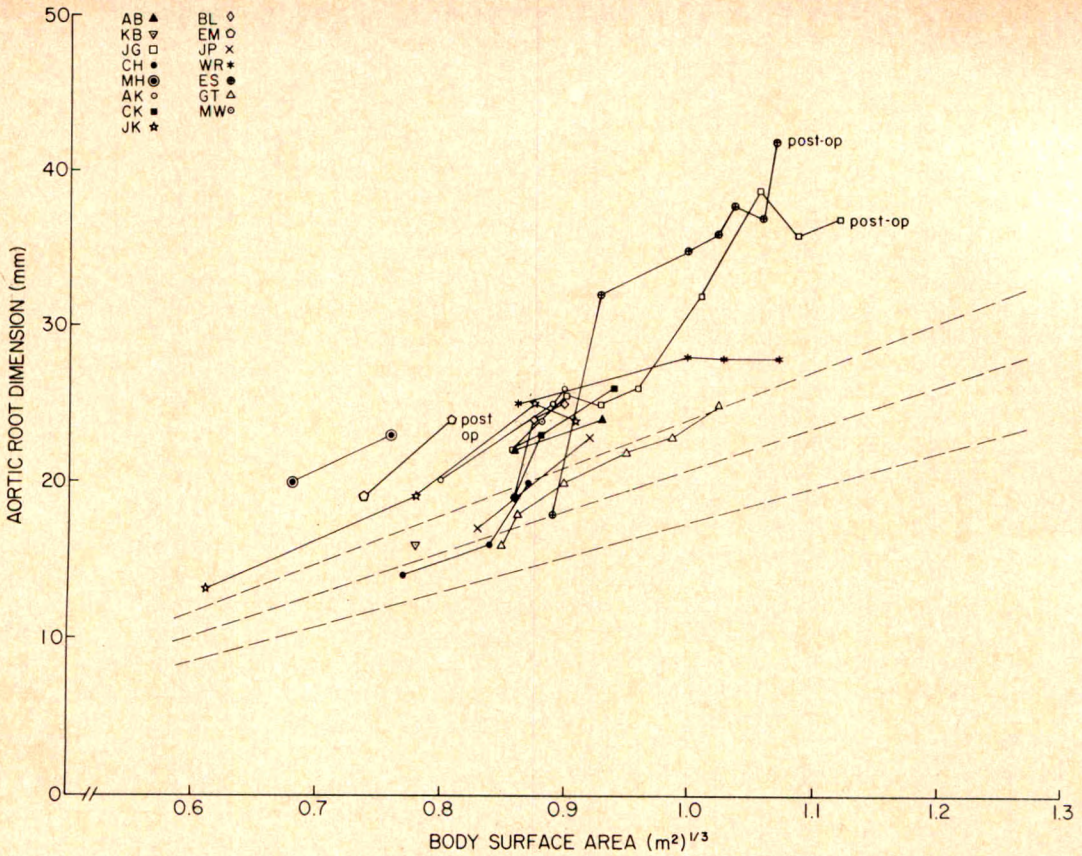

FIGURE 1. Aortic root diameter in the Marfan syndrome. M-mode echocardiographic aortic root dimension is plotted versus the cube root of body surface area. Three patients who had postoperative (post-op) echocardiography after mitral valve replacement are indicated. Patient 1 (MH) died shortly after mitral valve surgery and did not undergo postoperative echocardiography. The **dashed lines** indicate the mean values and 95% prediction intervals for aortic root dimension in normal children.

Sporadic cases of the Marfan syndrome tend to be more severely affected, on an average, than familial cases[1,2] and account for about one third of patients of all ages with Marfan syndrome. Eight of 15 of our patients did not have an affected parent, but were referred for management of specific problems, 4 for heart murmurs. The fact that more than half of our patients were sporadic suggests a possible sampling bias. This disparity may be related to the young age of our population and expression of the more afflictive phenotype at an earlier age. Sporadic and familial cases were first evaluated at the same mean age (19 months) when only sporadic cases had MR (5 versus 0), whereas aortic root dilatation and MVP on echocardiographic examination were similar in both groups (4 versus 3) and (5 versus 4). All 4 patients who required mitral valve replacement were sporadic. Whether clinical differences in sporadic versus family history cases reflect genetic heterogeneity will be answered when basic defects or their molecular markers are discovered.[31]

Aortic dilatation: In this study, almost all patients had aortic root dilatation. Only 1 patient had AR detected with auscultation. This patient also had the largest aortic root diameter (3.5 cm/m^2) when the murmur was first heard, in keeping with preliminary evidence that AR results from progressive stretching of the upper cusp attachments around the sinotubular ridge.[32]

To assess changes in aortic root dimension with increasing body surface area, measurements from all echocardiograms were plotted (Fig. 1). For 6 patients, the slope of the line was normal, although the aortic root diameters were all >95% prediction intervals for normal children. Seven patients showed periods during which the slope of the line was increased, a finding not likely to be due to growth. The regression equation with 95% prediction intervals, derived from the data of Henry et al,[18] for normal children that predict aortic root diameter from body surface area is 26.8 [BSA$^{1/3}$] − 6.1 ± 16%. Overall, for our study group at latest follow-up, the regression equation is 68.0 [BSA$^{1/3}$] − 38.6, indicating both a greater aortic root dimension and a greater slope.

Aortic root dilatation is the most common cardiovascular abnormality in adult patients with Marfan syndrome.[2,13,14] This study shows that aortic root dilatation is already manifest in early childhood in most patients. There are isolated studies of patients with gross dilatation of the sinuses of Valsalva and histopathologic characteristics of medial degeneration present in utero.[1,33] Thus, aortic root dimension is an objective criterion of the Marfan syndrome, even in

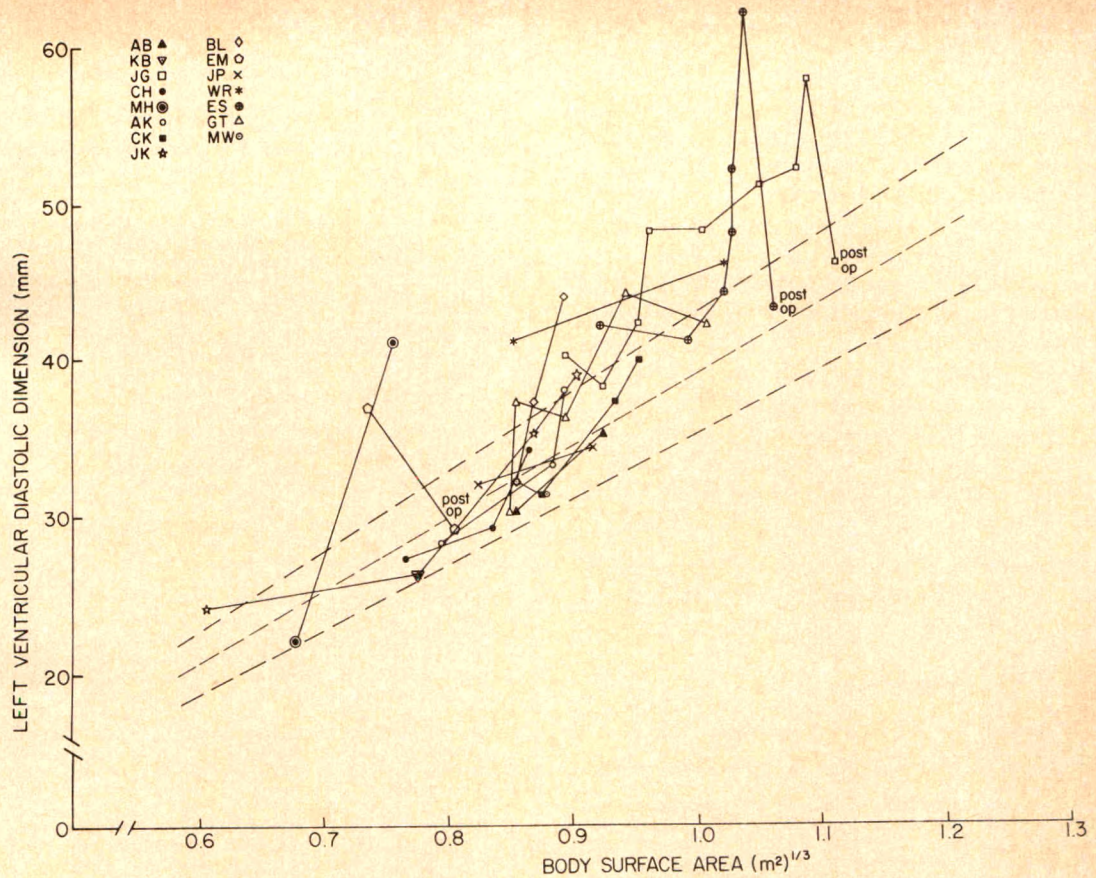

FIGURE 2. Left ventricular end-diastolic dimension in the Marfan syndrome. M-mode echocardiographic left ventricular end-diastolic dimension is plotted versus the cube root of body surface area. Three patients who had postoperative echocardiography after mitral valve replacement are indicated. Patient 1 (MH) died shortly after mitral valve surgery and did not undergo postoperative echocardiography. The **dashed lines** indicate the mean values and 95% prediction intervals for left ventricular end-diastolic dimension in normal children.

infancy. Moreover, the aortic root progressively enlarges in the pathologic range throughout childhood, a process which, when accelerated, may lead to AR before adolescence.

No child in this study required aortic surgery. Our criteria for performing elective, prophylactic repair of the ascending aorta with a composite graft are moderate AR and sinus of Valsalva dilatation of about 5.5 cm.[34] Periodic clinical and echocardiographic evaluation of all patients of any age with Marfan syndrome is mandatory to establish the optimal time for surgical intervention. For the child without AR, an annual echocardiogram is recommended.

Mitral valve dysfunction: Involvement of the mitral valve is almost as common as aortic root dilatation in the Marfan syndrome and may be severe enough to represent the major cardiovascular morbidity, particularly in children.[6,20,23,25,27–29,35,36] In a longitudinal review of 120 patients <22 years, mitral valve dysfunction in the Marfan syndrome presented as MVP and, as opposed to idiopathic MVP, progressed clinically in about half.[37]

Within the group reported here, 5 children progressed from having no to definite auscultatory or echocardiographic evidence of MVP. Five girls had MR when first evaluated (mean age 18 months); 4 developed more severe valvular dysfunction, congestive heart failure, and progressive left ventricular dilatation. All had successful mitral valve replacement (mean age 78 months). One died soon after operation at age 11 months and, in retrospect, surgery might have been indicated earlier because of severe failure to thrive. A marked reduction in left ventricular diastolic dimension followed valve replacement in all 3 survivors. Although the 4 patients who had severe mitral valve dysfunction were female, males have MVP and MR nearly as frequently as females.[37] We cannot be certain from our series or from the literature whether the early and severe MR in some females reflects true sex influence on phenotypic expression, variability due to genetic heterogeneity or sampling bias. Idiopathic MVP is expressed more frequently, if not more severely or earlier, in females.[38,39]

Mitral valve replacement in young children is usually accompanied by 3 considerations for the long term. First, because the homograft valve tends to calcify or otherwise degenerate and because of the substantial life expectancy of the young patient with Marfan syndrome, we have routinely implanted the St. Jude Medical prosthesis. Second is the need for long-term anticoag-

ulation. Third is the potential development of valve-patient mismatch as the child grows, which should not be a problem in the Marfan syndrome because the anulus undergoes substantial dilatation and will accept prosthetic valves of diameter sufficient for hemodynamic function in adulthood. Another consideration unique to the Marfan syndrome is best illustrated by Patient 2 in this series. Regardless of mitral valve dysfunction, the aortic root will likely progressively dilate and lead to a need for composite repair. When mitral dysfunction is early and severe, the patient will require 2 separate procedures. However, for selected patients it may be possible to delay mitral repair until the patient is also a candidate for aortic surgery and to perform a combined procedure. On the other hand, it is probably unwise to delay aortic repair in anticipation of progressive mitral valve dysfunction because of the risk of aortic catastrophe once the root is markedly dilated.

Physical Conditioning and Left Ventricular Performance in the Elderly: Assessment by Radionuclide Angiocardiography

DOUGLAS D. SCHOCKEN, MD, JAMES A. BLUMENTHAL, PhD, STEVEN PORT, MD, PAULA HINDLE, MSN, and R. EDWARD COLEMAN, MD

In contrast to young persons, normal elderly persons who undergo symptom-limited dynamic exercise demonstrate a decrease in left ventricular (LV) contractile performance characterized by a decrease in LV ejection fraction. To test the hypothesis that physical conditioning can be achieved in older persons and produces improvement in the exercise-induced decrease in LV ejection fraction observed during normal aging, we examined 24 normal elderly persons (mean age 72.0 years) before and after a 12-week program of physical training. The subjects had been screened for evidence of cardiovascular disease including rest and exercise stress electrocardiograms. All subjects underwent rest and exercise upright sitting radionuclide angiocardiography before and after the training program.

The subjects achieved cardiovascular training effects as measured by increased functional capacity and decreased double product at one-half the maximum work load attained at the initial stress test. A significant increase occurred after training in the cardiac index response to exercise ($p < 0.02$) and in the augmentation of the end-diastolic volume index produced by exercise ($p < 0.05$). However, the exercise-induced decrease in LV ejection fraction and increase in LV end-systolic volume index remained unaltered by training.

In conclusion, although older persons can achieve overall training effects from a program of physical conditioning, the age-associated differences in LV contractile performance remained unchanged. Our data suggest that deconditioning is not a significant contributor to the decline in LV contractile performance in the elderly.

A decline in cardiovascular performance is a general phenomenon of the aging process, including decreased cardiac output and heart rate.[1,2] In response to dynamic exercise, significant reductions in maximal oxygen consumption, heart rate, and cardiac output have been well documented.[3,4] In addition, a recent study from our laboratory used radionuclide angiocardiography (RNA) to demonstrate a diminution in left ventricular (LV) ejection fraction in response to exercise in a group of untrained elderly persons free of overt cardiovascular disease.[5] Possible mechanisms for age-associated changes in cardiovascular function are numerous and include decreased intrinsic contractility, altered preload or afterload, altered sympathetic responsiveness, chronic deconditioning, and clinically unrecognized cardiac disease.

Physical conditioning is a long-recognized method of improving cardiovascular performance. Its beneficial effects are well documented in the young.[6] Features of the cardiovascular response to conditioning include increased oxygen extraction and systemic arteriovenous oxygen difference which, along with enhanced stroke volume and maximum cardiac output, result in augmented maximal oxygen consumption. Some clinical observations supporting these changes consist of diminished heart rate at rest, increased functional capacity, and rapid return to resting hemodynamic status after acute exercise. Radionuclide ventriculography demonstrates augmented cardiac output and increased end-diastolic volume in response to exercise in young athletes after high-intensity physical conditioning.[7] In middle-aged patients with coronary artery disease, physical conditioning increases functional capacity, although its specific effects on ventricular function are less uniformly recognized.[8–10] Some studies[11,12] support

the view that older persons cannot achieve training effects by physical conditioning. However, others[13–15] suggest that the elderly can indeed achieve a state of physical conditioning.

Methods

Subjects: Forty-two subjects aged ≥65 years were recruited primarily from 3 sources: a volunteer pool from the Duke University Center for the Study of Aging and Human Development, residents of the North Carolina Methodist Retirement Home, and participants in the Duke Institute for Learning in Retirement. All potential subjects underwent initial evaluation including medical history, physical examination, and electrocardiography at rest and during upright sitting bicycle ergometry as will be described. Criteria for exclusion from the exercise program consisted of historical or physical evidence of cardiovascular disease, active disease known to affect the cardiovascular system, medications known to influence cardiovascular function, and electrocardiographic changes interpreted as indicative of ischemic heart disease at rest or during exercise. Fifteen subjects were excluded from participation on the basis of these criteria. The ages, clinical status, and previous activity levels of subjects from all sources were similar. Consequently, the results reflect pooled data from all 3 sources.

Radionuclide angiocardiography: First-pass radionuclide angiocardiograms were obtained using a multicrystal gamma camera (System Seventy-Seven, Baird-Atomic, Inc.) fitted with a 2.54-cm parallel-hole collimator.[16] Each study was performed by the rapid bolus injection of a small volume containing 10 mCi of technetium-99m pertechnetate into an indwelling catheter placed in an external jugular or antecubital vein. Data were acquired at a framing rate of 25 ms for a total of 1 minute for each study. All subjects were studied in the upright sitting position from an anterior projection.

Computer processing of the data collected from each study used the Baird-Atomic System Seventy-Seven clinical software package. Briefly, a curve of count changes in the left ventricle was used to determine end-systolic times of individual beats. Data from 3 to 6 beats were superimposed to form a background-corrected representative cardiac cycle. A 21% isocount line delineated the end-diastolic and end-systolic measurements of the left ventricle. Volume determinations applied the area-length method of Sandler and Dodge[17] to end-diastolic and end-systolic edge contours. Those contours were determined with a sonic digitizing device coupled to a PDP-11/45 computer. Regional wall motion was analyzed by a review of videotape display of 21% isocount contours of sequential cardiac cycles. Regional function was also analyzed by calculating ejection fraction for each crystal conforming to the left ventricle image. The ejection fraction was displayed on a 16-color-coded scale, each color denoting a 6.25% difference in ejection fraction.

Exercise testing protocol: Rest and exercise studies were carried out on an upright isokinetic bicycle ergometer (Fitron, Lumex). The electrocardiogram (routine limb leads and V_5 and V_6) was monitored for rate, rhythm, and S-T segment changes at rest throughout the period of exercise and until the heart rate had returned to the preexercise baseline level. Blood pressure was monitored by a cuff sphygmomanometer throughout the testing and post-testing period. After a radionuclide angiocardiogram at rest, each subject was then instructed to pedal against work loads beginning with 100 kpm/min (980 J) and incrementally augmented thereafter until exhaustion. Exercise radionuclide angiocardiography was performed at the maximal symptom-limited work load achieved. Exercise testing was repeated at the conclusion of the physical conditioning program with a slight modification. The resting study was performed as just described, whereas the exercise radionuclide angiocardiography was acquired at the same level of work load as the maximum achieved in the pretraining study.

Physical conditioning program: The subjects participated as a group in 3 exercise sessions per week for 12 consecutive weeks. Each period consisted of several minutes of stretching exercise and warmup on bicycle ergometers at no work load. The aerobic portion of the session consisted of 25 to 30 minutes of continuous pedaling at a fixed rate against predetermined tension, so that each participant's heart rate would be maintained within a training range (70 to 85% of heart rate achieved at the time of initial bicycle ergometer testing). Radial pulse was monitored during each training session and work loads were adjusted on a weekly basis to maintain the heart rate in the training range. Each training session concluded with a brief period of "cool down" bicycling without tension. All sessions were supervised by at least 2 observers trained in acute cardiac care.

Statistical analysis: The data were largely examined by analysis of variance. Because men and women may have responded differently to the training program, gender (male and female) was considered a between-subject factor. Similarly, because older subjects may have shown a different pattern of response compared with younger subjects, age (≤70 years old and >70 years old) was also considered a between-subject factor. Time (before and after training) served as a within-subject factor, so that main effects for time indicated significant changes before and after training. State (at rest and during peak exercise) also served as a within-subject factor for variables in which change from rest to exercise was considered to be important. Chi-square analyses were used to analyze a selected matrix of segmental wall motion abnormalities.

Results

Of 27 subjects initially enrolled in the exercise program, 24 (18 women, 6 men; mean age 72.0 ± 6.2 years) completed the study. Two participants had dropped out for medically unrelated reasons, and 1 was not included because of medication use unknown to the investigators until after enrollment. Attendance at the exercise training sessions was excellent, with all subjects participating in at least 90% of the scheduled sessions. No injuries or morbid cardiac events occurred during the entire study.

Physical conditioning: Physical conditioning was assessed by work load on the bicycle ergometer and rate-pressure product at a matched submaximal work load. Both of these variables improved when initial and final bicycle ergometer results were compared. Work load on the bicycle increased from 690 ± 151 kpm/min to 758 ± 141 kpm/min ($p < 0.008$), and rate-pressure product at matched submaximal work load decreased from 14,300 ± 3,070 to 13,400 ± 2,230 ($p < 0.02$). Other physiologic variables of cardiovascular performance measured before and after training are depicted in Table I. Analysis of variance disclosed no significant interactions attributable to sex difference or age stratification, suggesting that both male and female subjects changed in the same way whether in the younger or older segment of our subject group. Consequently, all analyses were collapsed over age and sex.

Radionuclide assessment of global LV performance: Each measure of cardiac function (LV ejection fraction, cardiac output, cardiac index, end-systolic

volume index, and end-diastolic volume index) was considered in a separate 2 by 2 analysis of variance. Table II presents the means and standard deviations for each variable at rest and at peak exercise before and after the 12-week conditioning program. Analysis of variance for cardiac output revealed a significant main effect for State ($F(1,20) = 131$, $p < 0.001$), with cardiac output increasing from rest to exercise. This increase in cardiac output in response to exercise was comparable before and after training, as evidenced by the absence of a State × Time interaction. However, analysis of variance for cardiac index revealed not only significant main effects for Time ($F(1,20) = 4.94$, $p < 0.03$) and State ($F(1,30) = 296$, $p < 0.0001$) but also a significant State × Time interaction ($F(1,20) = 5.22$, $p < 0.03$). Analysis of simple effects revealed that although resting cardiac index remained constant before and after training, the cardiac index during exercise increased from 5.89 ± 0.97 liters/min/m^2 to 6.71 ± 1.71 liters/min/m^2 after training ($F(1,20) = 6.19$, $p < 0.02$), accounting for the significant interaction.

End-systolic volume index did not change over Time, although there was a significant State main effect ($F(1,20) = 22.3$, $p < 0.0001$); that is, there was a significant increase in end-systolic volume index from rest to exercise. In the absence of a significant interaction, it was apparent that this increase in systolic volume index was unchanged before and after training. However, consideration of end-diastolic volume index revealed a significant main effect for State ($F(1,20) = 34.2$, $p < 0.0001$) and a significant Time × State interaction ($F(1,20) = 6.25$, $p < 0.02$). Examination of simple effects revealed that although the resting end-diastolic volume index did not change from before to after training (59.4 ± 8.5 ml/m^2 to 57.9 ± 13.0 ml/m^2, difference not significant), the end-diastolic volume index did increase significantly during exercise, from 67.9 ± 14.4 ml/m^2 to 76.6 ± 20.2 ml/m^2 ($F(1,20) = 4.26$, $p < 0.05$) after the conditioning program.

LV ejection fraction demonstrated main effects for both Time $F(1,20) = 6.55$, $p < 0.03$) and State ($F(1,20) = 10.65$, $p < 0.003$). However, no significant interaction was seen between Time and State. In other words, the decrease in LV ejection fraction of these elderly subjects in response to exercise persisted unaltered despite physical conditioning.

Radionuclide assessment of regional wall motion: Regional wall motion abnormalities were not commonly seen in the resting studies. Twenty-one subjects demonstrated no wall motion defect at rest before or after training. As shown in Table IIIA, a single subject had a wall motion abnormality at rest before and after the

LVEF = left ventricular ejection fraction.

training program, and 1 subject each developed or apparently resolved a resting wall motion defect during the course of the training protocol. No alterations in clinical status or electrocardiograms accompanied the changes in radionuclide results.

Table IIIB depicts the training effects on regional wall motion in response to exercise. Two subjects had studies technically inadequate for wall motion analysis. As in the resting studies, participants tended to have normal wall motion with exercise before and after training or abnormal wall motion, uninfluenced by training. However, 7 subjects with pretraining focal wall motion abnormalities had no defects when exercised to the same work load after training. Two subjects demonstrated previously undetected abnormal wall motion after training. The chi-square value for this analysis was not significant ($p > 0.40$). However, the small number of subjects in each cell may preclude meaningful statistical interpretation of these results.

We further examined the effect of conditioning on the LV ejection fraction response of subjects who had shown exercise segmental wall motion abnormalities before training. The subjects were divided into 2 groups based on the absence (Group A, n = 13) or presence (Group B, n = 11) of wall motion abnormalities with exercise before training. However, no significant difference appeared between the groups' LV ejection fraction responses to exercise before or after conditioning (Table IV).

Discussion

Our study confirms and extends earlier published work from this laboratory that documented the decrease in LV contractile performance in response to exercise seen in healthy aging subjects.[5] In addition to a decrease in LV ejection fraction with exercise, we showed that decreases in end-systolic volume observed in the young during exercise[7] do not occur in the elderly. The current study demonstrates that although elderly persons can achieve physical conditioning effects, the decline in LV performance in response to exercise persists.

Comparison of physical conditioning response in the elderly to other subject populations: The results of the present investigation prompt comparison to previous studies in 2 other groups, young healthy persons and patients with coronary artery disease. After training, young conditioned male athletes demonstrated decreased resting heart rate and LV ejection fraction, whereas resting end-systolic and end-diastolic volume increased with the net result being an unaltered resting cardiac output.[7]

In contrast, the present study shows that resting heart rate, cardiac index, and volume indexes remained unchanged in the elderly, whereas resting LV ejection fraction increased. The present findings are consistent with the response reported by Verani et al[10] for training effects in patients with documented coronary artery disease. The failure of rest end-diastolic volume to increase with training in the elderly may be a reflection of diminished diastolic compliance of the older ventricle in the resting state.

With regard to the exercise response after training, the elderly demonstrated unchanged heart rate and LV ejection fraction, while cardiac output increased because of minor augmentation in both end-diastolic and stroke volume. This observation at a work load matched to the pretraining maximal work load resembles the response of the young to post-training maximal work load. In our elderly subjects, the exercise-induced decline in LV ejection fraction and the concomitant failure to decrease end-systolic volume resembled the response noted in patients with coronary artery disease.[16] The overall change in LV ejection fraction from the resting state to exercise was unaffected by conditioning in the elderly, analogous to findings in patients with coronary artery disease.[9] By way of speculation, adaptation of the aging ventricle may confer minimal ability to dilate in response to stress but without concomitant ability to increase contractile performance.

As might have been expected, resting wall motion abnormalities were rarely seen in our subjects either before or after training, distinct from patients with coronary disease. Furthermore, patients with coronary artery disease have improvement in resting wall motion with training.[10] After conditioning, most of the subjects' wall motion in response to exercise remained unchanged (n = 13) or improved (n = 7), whereas 2 subjects displayed previously undetected wall motion abnormalities, an overall finding similar to those of Verani et al.[10] A cautionary note seems warranted in this discussion.

Reasonable care must be used in interpreting all minor changes in the radionuclide angiocardiographic studies of the elderly after training, because apparent statistical significance may not confer physiologic or clinical relevance.

Possible causes of the age-related decline in cardiac performance: Several factors, both methodologic and biologic, may explain our inability to induce improvement in ventricular performance in this elderly population after training. With respect to the present method, an easily conducted protocol was felt necessary to discourage dropouts in these elderly subjects. However, in contrast to results in younger individuals, 12 weeks of training may not be a enough to achieve optimal conditioning effects in the elderly. The current study is unique in testing elderly persons with upright sitting ventriculography at rest and with exercise using stress identical to that used in their physical conditioning program. A previous report from this institution documented the reproducibility of upright sitting radionuclide ventriculography at rest and with upright bicycle ergometry exercise.[18]

LV ejection fraction is one index of LV contractile performance. The determinants of LV contractile performance include preload, afterload, and contractile state. Biologic factors that might influence these determinants to prevent significant conditioning-induced modification of LV performance in response to exercise include: (1) inability of the heart to respond to the repetitive sympathetic stimulation associated with cardiovascular training, (2) decreased response to augmented preload by the Frank-Starling mechanism, (3) inability to respond to exercise-induced increase in afterload, (4) decreased overall contractility rendering specific myocardial training unattainable, (5) inability to improve myocardial oxygen extraction, (6) occult coronary artery disease, and (7) a state of chronic deconditioning in the elderly that is less readily reversed than in younger persons.

Loss of sympathetic responsiveness to catecholamines occurs during aging.[19] This change has been attributed to mechanisms both dependent[20] and independent[21] of alterations in adrenergic receptors. A failure of the Frank-Starling mechanism could account for inability of the older ventricle to respond to stress in a manner similar to that of the young ventricle. However, the minimal increase in stroke volume produced by augmented end-diastolic volume with exercise achieved by training in the elderly suggests a response similar to the training effect observed in young athletes. As such, current observations on changes in end-diastolic volume from rest to exercise in the pre- and post-training period do not support a significant decrement in the Frank-Starling mechanisms. Despite the failure of exercise to induce a decline in end-systolic volume in this study, afterload (as reflected in the blood pressure response) does not demonstrate changes with exercise after training in our subjects. Using an animal model, Yin et al[22] described increased aortic impedance in response to exercise in old dogs. In addition, in vitro preparations of senescent rat hearts display decreased compliance and augmented stiffness characteristics.[23] These 2 studies may have implications for the description of cardiac performance in aging man. The investigation reported herein does not address decreased myocardial oxygen extraction as a potential cause of the decrease in LV contractile performance. Hartley et al[24] suggested that inability to increase the systemic arteriovenous oxygen difference may indeed be an important factor in the failure to achieve more significant cardiovascular training in the elderly. The present study cannot exclude this possibility.

Occult cardiovascular disease may explain a diminished overall training effect or the ability to influence global or regional LV performance. Probability alone predicts a significant prevalence of coronary artery disease in this age group. However, all the subjects were asymptomatic, without significant physical findings, and each failed to demonstrate evidence of ischemic heart disease on electrocardiograms at rest or during stationary bicycle exercise. These findings decrease somewhat the likelihood of encountering occult coronary disease in this population.

Coronary artery disease per se should not prevent the attainment of a training effect. Studies have demonstrated the ability to achieve physical conditioning in patients with documented coronary artery disease.[8,25] Despite the overall physical conditioning attained in those patients with coronary artery disease, few studies have shown meaningful improvement in either global or regional LV performance by physical conditioning in patients with coronary artery disease.[9,10] The present study suggests that the postconditioning changes in overall cardiovascular performance and LV contractile performance of asymptomatic clinically disease-free elderly persons minimally resembles the training responses seen in both young athletes and middle-aged patients with coronary artery disease. The significance and implications of these possible similarities are not entirely apparent. Additionally, the role of life-long physical conditioning in preventing or retarding the observed decline in LV contractile performance remains untested in man.

Deconditioning per se would not appear to be either the sole or the major determinant of decline in LV contractile response to exercise observed in older man. Further studies directed at noninvasive assessment of ventricular compliance characteristics and overall contractility appear to be one fruitful approach to the perplexing problem of waning cardiovascular performance during senescence.

Acknowledgment: The coordinated efforts of numerous persons were required to complete this study. Unfortunately, because of the lack of space here, many will go individually unrecognized. However, we gratefully acknowledge Drs. Robert Nebes and Donald Neisch for permission to study their patients, Rosemarie Schuler, NMT, and the staff of the Nuclear Cardiology Laboratory, Duke University Medical Center, for their cheerful and competent technical skills, Dr. Frederick R. Cobb for his thoughtful criticism, F. Paul Koisch, without whose help the training sessions could not have been conducted, Paula Crockett, RN, for assisting in supervising the exercise sessions, Terri Needels, PhD, and Leslie C. O'Toole for their assistance in computer programming and data

analysis, and Maria Gaines for her expert secretarial work. We specifically acknowledge the encouragement, guidance, and fiscal support provided by Drs. Andrew G. Wallace and Robert H. Jones.

Abnormal Thallium-201 Scans in Patients With Chest Pain and Angiographically Normal Coronary Arteries

BRUCE C. BERGER, MD, RICHARD ABRAMOWITZ, MD, CHAN H. PARK, MD, ANIL G. DESAI, MD, MARK T. MADSEN, PhD, EDWARD K. CHUNG, MD, and ALBERT N. BREST, MD

We reviewed the exercise thallium-201 (Tl-201) scans and clinical data of 41 patients with chest pain and normal coronary arteries to identify clinical factors associated with "false-positive" studies. Exercise Tl-201 studies were performed before angiography and often precipitated referral. Sex, beta-blocker therapy, anginal pattern, and results of exercise electrocardiography were evaluated and compared with Tl-201 imaging. A negative Tl-201 study was the most common finding ($p < 0.005$). Of the 41 patients, 11 (27%) had abnormal exercise Tl-201 scans. No clinical factor was significantly associated with a false-positive Tl-201 scans. Of the 11 patients with abnormal scans, 9 had ≥1 cardiac abnormality: right bundle branch block in 2, mitral valve prolapse in 3, paroxysmal atrial fibrillation in 2, abnormal left ventricular diastolic pressure in 3, and left bundle branch block in 1. Thus, (1) when results of exercise Tl-201 imaging are used to refer patients for angiography, "false-positive" Tl-201 studies are common; (2) sex, beta blockade, anginal pattern, and results of exercise electrocardiogram are not useful predictors of a false-positive Tl-201 study; and (3) patients with chest pain, normal coronary arteries, and abnormal Tl-201 scans frequently have other cardiac abnormalities.

The use of thallium-201 (Tl-201) myocardial perfusion imaging in the evaluation of patients with chest pain has significantly increased our ability to detect coronary artery disease (CAD).[1–3] Patients with abnormal Tl-201 scintigrams are frequently referred for coronary angiography. Patients with normal exercise Tl-201 scintigrams have an excellent prognosis in the following 2 years[4] and often are not studied further. We recently noted an increase in the number of patients with abnormal exercise Tl-201 scans and normal coronary arteries. Because the factors that affect the specificity of exercise Tl-201 imaging have not been clarified, we attempted to correlate the results of Tl-201 imaging with exercise electrocardiography and with various clinical characteristics in this group of patients with chest pain and normal coronary arteries.

Methods

Patient population: One hundred fifteen patients with chest pain who underwent coronary angiography also underwent exercise electrocardiography (ECG) and Tl-201 scintigraphy. Patients with valvular heart disease or cardiomyopathy known before angiography were excluded. Forty-one of these patients had no significant (≥50% stenosis) CAD and form the basis of this report.

All 41 patients had exercise Tl-201 and ECG testing ≤4 weeks before catheterization. There were 18 men and 23 women, with a mean age of 53 years (range 27 to 73). No patient had a history or electrocardiographic evidence of myocardial infarction.

Rest and exercise electrocardiography: Rest and exercise electrocardiograms were interpreted by 2 of the investigators without knowledge of the scintigraphic or angiographic results. Q waves ≥0.04 second on the resting electrocardiogram were considered diagnostic of previous myocardial infarction. Patients exercised in the fasting state on a treadmill using the Chung protocol,[5] but medications were not discontinued. Exercise was stopped if the patient achieved the target heart rate or if chest pain or fatigue developed. Leads II, V_3, and V_6 were monitored during exercise and a 12-lead electrocardiogram was recorded immediately before and after exercise. Test results were considered positive, negative, or nondiagnostic according to standard criteria.[5]

Imaging protocol: Patients were injected at peak exercise with 1.5 mCi of Tl-201 followed by a 10-ml saline flush and continued walking for 30 to 60 seconds. Imaging began within 10 minutes of injection in the anterior view, followed by the 40° and 60° left anterior oblique views. Anterior and 40° left anterior oblique views were repeated immediately. If an abnormality was detected on initial images or washout curves (to be described), delayed images were obtained 2.5 to 3 hours after injection. Images were recorded for 10 minutes on a portable gamma camera with a general all-purpose collimator and a 25% window centered on the 80-KeV energy peak. Images were produced on conventional transparency film and

stored in a computer for image processing and quantitative analysis.

Image analysis: All studies were interpreted jointly during clinical reading sessions by 3 of the investigators who were unaware of the exercise electrocardiogram results. Unprocessed images and quantitative data were used to produce the final interpretation. Quantitative analysis of Tl-201 uptake and washout was performed using the horizontal profile method as described and applied by Berger et al[3] and Watson et al.[6] Decreases in Tl-201 activity thought to be due to breast shadow or valve plane were not read as abnormal. Isolated persistent apical defects were also not read as abnormal because apical thinning may be a normal variation.[7]

Cardiac catheterization: Selective coronary arteriography was performed using the Sones or Judkins technique. Ventriculography was performed in the 30° right anterior oblique projection. Cineangiograms were interpreted independently by 2 observers. Coronary artery stenosis were considered significant when luminal narrowing was ≥50%.

Results

Thallium-201 imaging: Eleven of 41 patients with chest pain but without significant CAD had abnormal Tl-201 images, for a specificity of 73%. Table I summarizes the clinical, electrocardiographic, and scintigraphic findings in the 11 patients with abnormal Tl-201 scintigrams. Seven women and 4 men had false-positive Tl-201 images. Six patients had 2 defects. Two-vessel CAD was suspected in 3 of these patients because defects were in the anatomic distribution of 2 coronary arteries. In the other 3 patients, 2 defects were thought to be caused by a single coronary stenosis because they occurred in the distribution of 1 vessel. Figure 1 is taken from a patient with typical angina and a negative exercise electrocardiogram. Left anterior descending and right CAD were suspected in this patient, who subsequently was found to have normal coronary arteries.

Of the 17 Tl-201 defects found in 11 patients, 12 defects demonstrated partial or complete redistribution and 5 defects were persistent. There were 5 septal defects, 5 inferior defects, 3 posterolateral defects, 3 apical defects, and 1 defect involving the anterolateral segment. All 3 defects involving the apical segments in our series showed redistribution and were associated with other defects, making it more likely that they were abnormal. None of the patients demonstrated abnormal lung uptake of Tl-201.

Of the 74 patients with CAD who underwent exercise Tl-201 imaging, abnormal uptake or washout, or both, was detected in 61, for a sensitivity of 82%, which is within the range reported in other studies.[1–3]

Resting electrocardiogram: Nineteen patients had abnormalities on the resting electrocardiogram. No patient had evidence of myocardial infarction. Two patients had right bundle branch block and 1 patient left bundle branch block. Three patients had ischemic T-wave inversions. Eleven patients had nonspecific T-wave abnormalities. Two patients had left axis deviation (≥ −15°). Twenty-two had normal electrocardiograms. Of the 11 patients with abnormal exercise Tl-201 studies, 6 had normal electrocardiograms, 2 had right bundle branch block, 1 had left bundle branch block, and 2 had nonspecific T-wave abnormalities. Figure 2 is an electrocardiogram from the patient with left bundle branch block. The Tl-201 scan shows a persistent septal defect.

Exercise electrocardiography: Eleven patients had false-positive exercise electrocardiograms, 17 patients had negative tests, and 13 tests were nondiagnostic. Thus, the specificity of the exercise electrocardiogram in this study was 73% and not significantly different from that of Tl-201 imaging. Of the 11 patients with abnormal Tl-201 images, 3 had positive exercise electrocardiograms, 5 had negative electrocardiograms and 3 were nondiagnostic.

Clinical characteristics: *Chest pain:* Eighteen patients had typical effort angina and 23 had atypical chest pain. Thirteen patients with typical angina and

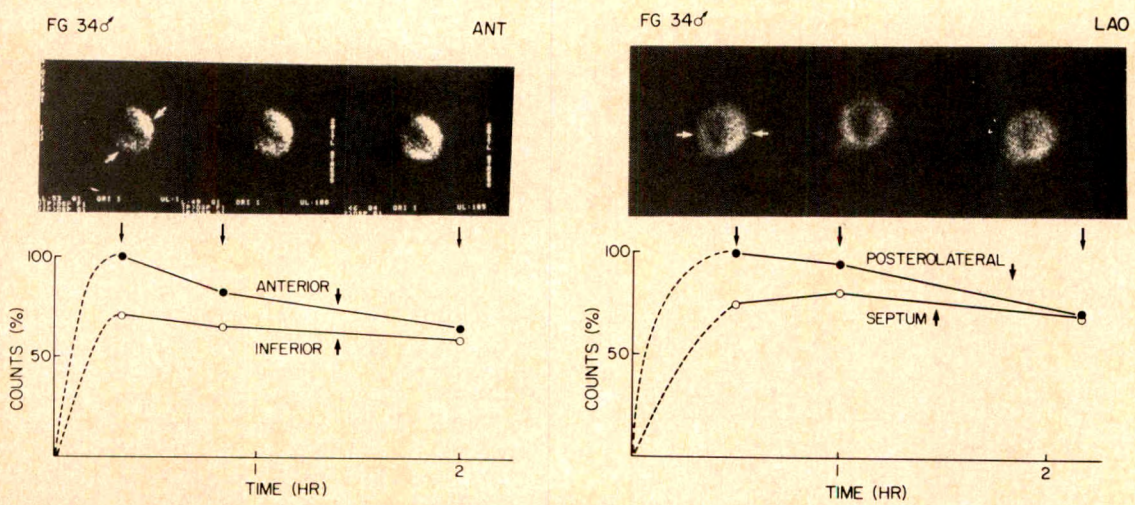

FIGURE 1. Sequential anterior (ANT) and 40° left anterior oblique (LAO) thallium-201 images after exercise and corresponding time-activity curves. Peak activity of 100% refers to the maximum segmental counts recorded during the imaging period. **White arrows** indicate the regions of interest from which the time-activity curves are derived. **Left,** the anterior view shows an initial inferior defect with redistribution on delayed views. **Right,** the left anterior oblique view shows an initial septal defect, which also fills in on delayed views. Right coronary and left anterior descending coronary disease were suspected.

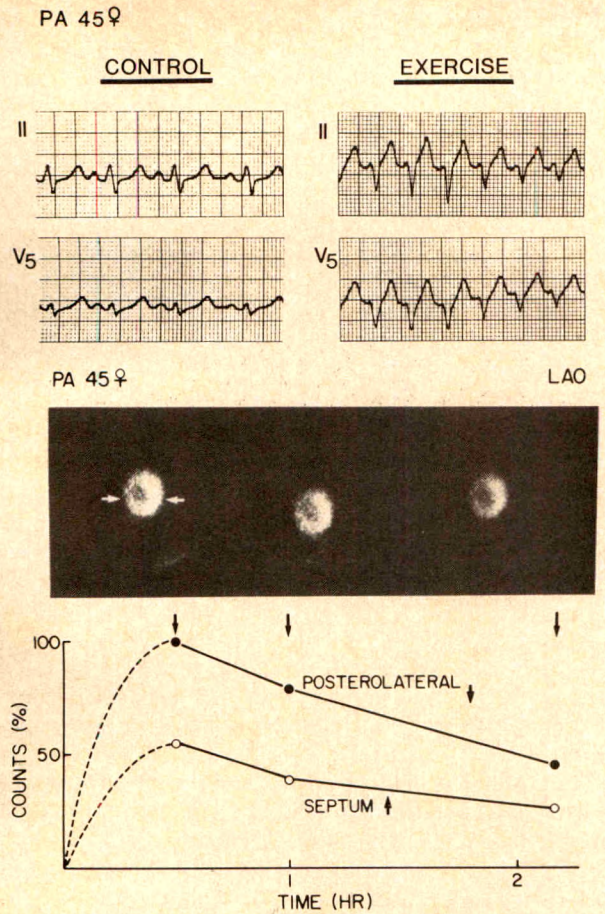

FIGURE 2. Top, control and exercise electrocardiograms in a patient with left bundle branch block. The heart rate increased from 95 to 160 beats/min. **Bottom,** sequential left anterior oblique (LAO) images obtained after exercise and displayed as described in Figure 1 demonstrate a persistent septal defect. Left anterior descending coronary disease was suspected.

17 patients with atypical chest pain had normal exercise Tl-201 scans. Of the 11 patients with abnormal Tl-201 images, 5 had typical angina and 6 had atypical pain. Three patients with typical angina (2 normal Tl-201 studies, 1 abnormal study) had been hospitalized previously with a diagnosis of unstable angina.

Sex: There were 23 women and 18 men in the study group. Seven women and 4 men had abnormal Tl-201 scans. Six women and 5 men had positive exercise electrocardiograms. In this study the specificity of the exercise electrocardiogram and the Tl-201 scan was the same in men and women.

Beta blockade: Twenty-two patients were taking beta-blocking agents (15 propranol, 4 metoprolol, 3 nadolol) and 19 were not. Medication was not stopped before testing. Seven of 11 patients with abnormal Tl-201 images and 15 of 30 with normal images took beta-blocking drugs. Thus, beta-blocking drugs did not influence the specificity of exercise Tl-201 imaging.

Cardiac catheterization: None of the patients had significant CAD. Six patients had 25 to 40% left anterior descending coronary artery lesions. Five of the 6 had normal Tl-201 scans and 1 (25% lesion) had a persistent septal defect. Two of the 6 had positive exercise electrocardiograms.

Thirteen patients had abnormal (>12 mm Hg) resting left ventricular end-diastolic pressure (LVEDP) measured after the "A" wave and before contrast injections. The LVEDP in this group ranged from 16 to 24 mm Hg. Three of these patients had abnormal exercise Tl-201 studies, including the patient illustrated in Figure 1.

Left ventricular wall motion was normal in 38 patients. Two patients had global hypokinesia (ejection fraction 38 and 45%). Their exercise electrocardiograms were normal. One patient had inferior akinesia. Ten of 11 patients with abnormal Tl-201 scans had normal wall motion. The patient with inferior akinesia had right bundle branch block, a nondiagnostic exercise electrocardiogram, and inferior and posterolateral defects.

Ergonovine testing was negative in 7 of 11 patients with abnormal Tl-201 scans. It was not performed in the other 4 patients. Metabolic studies were not performed in our patients.

Miscellaneous findings: Echocardiography was performed in 30 of the 41 patients. Five patients had mitral valve prolapse and 3 of these had Tl-201 scan defects (Table I). One patient with left ventricular hypertrophy on echocardiography had a normal rest and exercise electrocardiogram and Tl-201 scan. There were 2 patients with a history of paroxysmal atrial fibrillation. Both had normal rest and exercise electrocardiograms, but their Tl-201 studies gave abnormal results.

In summary, 9 of 11 patients with abnormal Tl-201 scans had ≥1 cardiac abnormality. Only 13 of 30 patients with normal Tl-201 scans had ≥1 cardiac abnormality ($p < 0.05$).

Discussion

Thallium-201 myocardial perfusion imaging is more sensitive and more specific than exercise electrocardiography in the detection of CAD.[1–3] It is particularly useful for evaluating patients with nondiagnostic or suspected false-positive exercise electrocardiograms.[3,8,9] For these reasons, exercise Tl-201 imaging is frequently used as an important aid in determining which patients with chest pain should be referred for coronary arteriography.

In a group of patients undergoing cardiac catheterization and angiography, we noted an unusually high number of false-positive Tl-201 images (27%). Thus, we have attempted to correlate the clinical and technical factors that may affect the specificity of Tl-201 scintigraphy.

Patient selection: One reason for the relatively low specificity (73%) for CAD in our study may have been patient selection. In previous studies evaluating sensitivity and specificity, exercise imaging was performed in patients referred for cardiac catheterization. In such patients, the prevalence of CAD is usually high. Tl-201 imaging is now used to help select patients for cardiac catheterization. Patients with clinical factors indicating a high probability of CAD or with a positive exercise electrocardiogram or positive Tl-201 scan are referred for catheterization. When chest pain is atypical and

TABLE I Clinical Correlations in 11 Patients With "False-Positive" Thallium-201 Scans

Case	Age (yr) & Sex	Pain	Beta-Blocking Drug	Rest ECG	Exercise ECG	Tl Study	Additional Findings
1	45F	A	+	LBBB	−	S-RD I-RD	. . .
2	47M	T	+	NL	0	I-PD	. . .
3	62F	T	+	NSTA	+	S-PD	. . .
4	68F	A	0	NSTA	0	P-RD	MVP on echo PAF
5	51M	T	0	RBBB	−	I-RD P-PD	Inferior akinesia
6	54F	T	+	NL	0	S-RD AP-PD	MVP on echo
7	34M	T	+	NL	0	S-RD I-RD	LVEDP = 20 mm Hg
8	64F	A	+	NL	+	AN-RD AP-RD	PAF
9	58F	A	+	NL	+	S-PD	LVEDP = 20 mm Hg
10	50F	A	0	NL	−	I-RD AP-RD	MVP on echo LVEDP = 20 mm Hg
11	49M	A	0	RBBB	0	P-PD	. . .

A = atypical; AN = anterior; AP = apical; echo = echocardiogram; I = inferior; LBBB = left bundle branch block; LVEDP = left ventricular end-diastolic pressure; MVP = mitral valve prolapse; NL = normal; ND = nondiagnostic; NSTA = nonspecific T-wave abnormalities; P = posterior; PAF = paroxysmal atrial fibrillation; PD = persistent defect; RBBB = right bundle branch block; RD = redistribution; S = septum; + = positive; 0 = negative; − = nondiagnostic.

adequate exercise electrocardiograms and scintigrams are negative, CAD can reliably be excluded in 94% of patients.[10] Further, Pamelia et al[4] observed only a 2% incidence of subsequent adverse cardiac events in the following 16 months in 351 patients with normal exercise Tl-201 scans. Thus, patients with normal exercise Tl-201 scans are frequently not referred for coronary angiography. Conversely, patients with positive Tl-201 scans may be referred for cardiac catheterization, even in the absence of other evidence of CAD. It is likely that many patients with chest pain, normal coronary arteries, and normal Tl-201 studies were not catheterized, whereas some with positive scans and a low likelihood of CAD were studied, causing our unusually low specificity.

Therefore, it is more appropriate at this time, when evaluating specificity, to use a group of patients with a very low (<2%) pretest likelihood of CAD based on clinical variables and the exercise electrocardiogram.

Clinical characteristics: In this study, a normal exercise Tl-201 study was the most common finding ($p < 0.005$) in patients without significant CAD when compared with other clinical characteristics frequently evaluated in patients with chest pain. Figure 3 summarizes the clinical data in 41 patients with chest pain and without significant CAD.

In the 11 patients with false-positive Tl-201 scans, none of the clinical findings were significantly different. Figure 4 shows that sex, beta-blocker therapy, type of

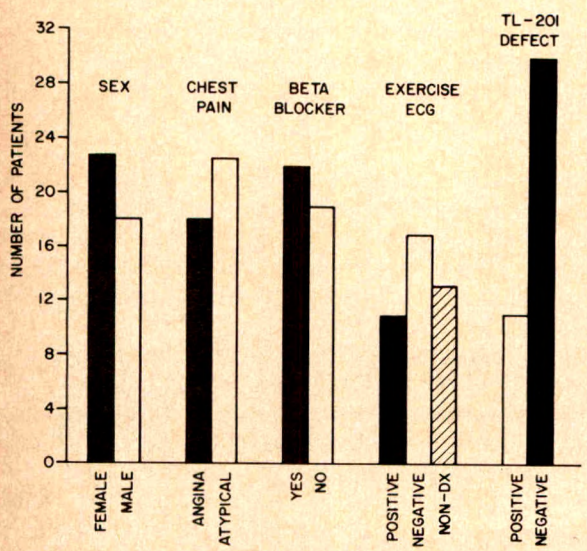

FIGURE 3. Summary of clinical data, exercise electrocardiogram (ECG), and thallium-201 (TL-201) results in 41 patients with chest pain and normal coronary arteries. A negative thallium-201 scan was the most common finding ($p < 0.005$). NON-DX = nondiagnostic.

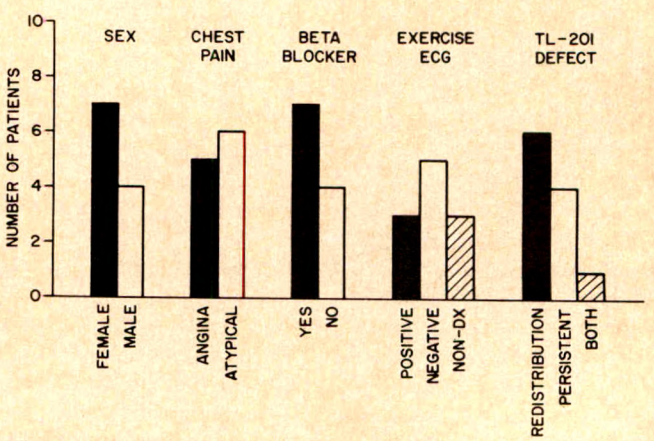

FIGURE 4. Summary of clinical data, exercise electrocardiogram (ECG), and thallium-201 (TL-201) results in 11 patients with false-positive thallium-201 images. None of the factors evaluated correlated with a false-positive thallium-201 study. ECG = electrocardiogram; NON-DX = nondiagnostic.

chest pain, exercise electrocardiogram results, and type of scan defect were not useful in detecting false-positive Tl-201 images.

Friedman et al[11] found the specificity of exercise Tl-201 imaging in women to be 88%. The specificity of the exercise electrocardiogram in women in their study was 41%. In our study, the specificity of Tl-201 imaging in women was lower at 70% (16 of 23), but not significantly different from the specificity in men (78%, 14 of 18). The exercise electrocardiogram in our study was equally specific in men and women (72 versus 74%). Although our results differ somewhat, both Friedman's study and ours demonstrate that exercise Tl-201 imaging is useful in women with chest pain.

A history of classic effort angina pectoris is quite specific for CAD.[12] In our 41 patients, almost half the patients had typical angina and typical angina was present in 45% of the patients with false-positive Tl-201 scans. Other investigators have had similar results.[13]

The effects of beta-blocker therapy on Tl-201 imaging are not clear. Osbakken et al[14] unexpectedly noted an increase in false-positive Tl-201 scans in patients taking propranolol. The mechanism was not explained. This finding was not confirmed in our study or those of others.[15]

Exercise electrocardiogram versus thallium-201 scintigraphy: In this study, the specificity of the exercise electrocardiogram and Tl-201 scintigraphy was the same (73%). However, the number of nondiagnostic exercise electrocardiograms decreased the diagnostic value of the test. It is in patients with nondiagnostic electrocardiograms that Tl-201 imaging may be most useful.[3,8] Interestingly, 3 patients with chest pain (1 typical, 2 atypical) and no significant CAD lesions had positive exercise electrocardiograms and positive Tl-201 scans, a combination that predicts coronary disease in 90% of patients.[16] All 3 patients were women, and all 3 had other cardiac abnormalities, as will be described.

Image interpretation: All exercise Tl-201 images were interpreted by visual inspection of unprocessed raw images as well as by quantitative analysis. This quantitative technique increases the specificity of Tl-201 imaging.[3] Additionally, defects considered to be due to obvious breast shadow or other soft tissue attenuation were not considered abnormal.

Dunn et al[17] reported that it was possible to distinguish false-positive Tl-201 defects by their "inconsistent" nature, that is, isolated apical defects or defects suspected of being due to soft tissue attenuation. However, of their 11 patients with "inconsistent" defects, 5 had scintigraphic evidence of ischemia, manifested by smaller defects on late images. We believe that exercise Tl-201 defects that demonstrate redistribution are usually due to CAD, and others agree that redistribution is usually a highly specific finding.[16] Further, in our patients there was no discernible change in chamber size, which may artifactually produce redistribution.[18]

All 11 of our patients with false-positive scans had defects believed to be consistent with CAD and 3 patients were thought to have 2 vessels involved because of the anatomic distribution of the defects. Thus, in our series, there was no pattern of image defect that reliably predicted a false-positive result.

Cardiac abnormalities: Although there was no significant CAD in our 41 patients, other cardiac abnormalities were frequently detected. Other investigators have detected abnormalities of myocardial flow reserve,[19] lactate production,[20] and abnormal myocardial biopsies[19,20] in patients with chest pain and normal coronary arteries. Some of the patients also had abnormal Tl-201 images.[20] Nine of our 11 patients with false-positive Tl-201 scans had at least 1 cardiac abnormality. Thirteen of 30 patients with normal scans and coronary arteries had a cardiac abnormality ($p < 0.05$).

Mitral valve prolapse: Three of 5 patients with mitral valve prolapse had positive Tl-201 images. Other studies have reported conflicting results of Tl-201 imaging in mitral valve prolapse.[21–23] Although the majority of patients with mitral valve prolapse and normal coronary arteries will have normal exercise Tl-201 images,[21,22] some patients with mitral valve prolapse and abnormal exercise Tl-201 scans have been reported.[23] The metabolic or myopathic abnormalities associated with mitral valve prolapse[24–26] may be the cause of these Tl-201 defects.

Catheterization abnormalities: One of our patients with a 25% lesion of the left anterior descending artery had a persistent septal defect. One patient with inferior and posterior Tl-201 defects had right bundle branch block and inferior akinesia. Coronary artery spasm and subsequent myocardial infarction could explain these findings, but neither patient had electrocardiographic evidence of myocardial infarction and the clinical history did not suggest variant angina. Further, ergonovine testing was negative in 7 patients with abnormal Tl-201 scans, including the 2 just mentioned. Ergonovine testing was not performed in the other 4 patients.

It is also possible that significant coronary stenosis was missed and that the angiogram was falsely negative, particularly in the 3 patients with positive electrocardiograms and Tl-201 scans. Except for the lesions noted, all patients had smooth arteries and no vessels were missing. Additionally, because of the exercise abnormalities, the angiograms were reviewed meticulously, particularly in the distribution of the scan defects. However, this does not exclude nonatherosclerotic forms of ischemia as the cause of the defects. Metabolic studies to evaluate flow reserve and lactate production were not performed.

Electrocardiographic abnormalities: Five of the 11 patients with false-positive Tl-201 scans had abnormalities of conduction or rhythm. Exercise Tl-201 imaging has been suggested as a means to evaluate chest pain in patients with conduction disturbances which render the exercise electrocardiogram nondiagnostic.[3,8] However, other workers have reported an increased incidence of false-positive Tl-201 scans in patients with left bundle branch block.[27] Two of 4 patients had paroxysmal atrial fibrillation and false-positive Tl-201 scans. Both were in sinus rhythm during exercise testing and the cause of the false-positive Tl-201 study remains unclear.

Left ventricular end-diastolic pressure: Thirteen of the 41 patients had abnormally elevated LVEDP. Three of these had abnormal exercise Tl-201 studies. Bush et al[28] report elevated LVEDP in 75 of 125 patients with chest pain and normal coronary arteries. Thirty-three of the 75 patients had angina during catheterization. Nitroglycerin decreased the filling pressure to normal and relieved the angina in all 33 patients. They did not report results of Tl-201 scintigraphy. The mechanism by which abnormal isolated diastolic dysfunction causes chest pain is undefined, but relief by nitroglycerin suggests ischemia may play a role. Similarly, ischemia may also explain Tl-201 image defects in some patients with chest pain, normal coronary arteries, and elevated LVEDP.

Clinical implications: Despite the efforts described to minimize the number of false-positive Tl-201 studies, a number of patients with chest pain and angiographically normal coronary arteries will demonstrate Tl-201 image defects. A normal exercise Tl-201 myocardial perfusion study is the most useful predictor of normal coronary arteries in patients with chest pain. Other clinical variables are not as helpful. However, patients with chest pain and normal coronary arteries frequently have other cardiac abnormalities that may represent nonatherosclerotic forms of ischemia or abnormal myocardial cellular metabolism. Such patients may have abnormal Tl-201 scintigrams.

The use of exercise Tl-201 imaging as a screening method in patients with chest pain will undoubtedly increase. This will probably result in the detection of increasing numbers of patients with abnormal Tl-201 images and normal coronary arteries. The high prevalence of cardiac abnormalities other than CAD in our study suggests that the true specificity of exercise Tl-201 imaging is undetermined and depends on the definition used.

Natural History of Platelet Deposition on Dacron Aortic Bifurcation Grafts in the First Year After Implantation

JOHN R. STRATTON, MD, BRIAN L. THIELE, MD, and JAMES L. RITCHIE, MD

This study defined the dynamics of platelet deposition on Dacron® arterial grafts up to 1 year after implantation in human subjects. Indium-111 platelet imaging was performed on 8 men 1 to 2 weeks after graft implantation and on 5 of these patients at a mean of 31 weeks (range 28 to 34) and again at 55 weeks (range 50 to 62). Serial imaging was performed at 24 to 96 hours after platelet labeling and injection in each study. Quantitative analysis was performed using a graft/blood ratio that compared background-corrected indium-111 platelet activity in the graft region to whole-blood indium-111 platelet activity. Additionally, blinded qualitative visual analysis of the images compared graft activity with the activity in adjacent native arteries. The mean of all graft/blood ratios (24, 48, 72, and 96 hours) progressively decreased from 4.4 ± 2.1 (±1 standard deviation) at 1 to 2 weeks to 3.0 ± 1.8 at 31 weeks ($p = 0.002$). There was no further decrease at 55 weeks (2.8 ± 2.0). For comparison, 12 normal subjects without grafts had a mean ratio of 1.8 ± 0.7. Visual analysis detected platelet deposition in 7 of 8 grafts at 1 to 2 weeks, 4 of 5 at 31 weeks, and 4 of 5 at 55 weeks. Deposition decreased qualitatively in 2 of 5 patients at late study. It is concluded that there is consistent, early platelet deposition on Dacron grafts in man. Although deposition decreases over 31 weeks, it remains readily detectable in most patients at 1 year. These findings suggest absent or incomplete endothelialization of the graft flow surface in humans in the first year after implantation.

The platelet response to recently implanted Dacron® arterial prostheses in humans has not been completely defined. In several animal models, platelet deposition occurs frequently in recently implanted prosthetic grafts,[1–7] but is rarely noted in chronically implanted grafts.[5,7–9] In animals, this decrease in platelet deposition over time is presumably due to the progressive endothelial coverage of the graft flow surface that occurs after implantation.[2,3,5–12] Experimental support for this hypothesis has come from studies in baboons and in dogs in which progressive endothelial coverage of the flow surface of Dacron grafts correlated well with normalization of platelet survival.[2,3]

In human subjects with recently implanted grafts, platelet survival times are decreased at 2 to 4 weeks after graft implantation, but normalize by 9 months.[3,13] However, the recent findings that indium-111–labeled platelet accumulation is detectable on chronically implanted Dacron grafts in patients indicates that platelet deposition continues beyond the period of shortened platelet survival, although possibly at a lesser rate.[14–18] This study quantitates the platelet deposition response to recently implanted Dacron aortic bifurcation grafts in human subjects and determines whether deposition decreases in the first year after implantation.

Methods

Subjects: Eight men, mean age 56 years (range 47 to 65), were studied. All had DeBakey knitted Dacron aortic bifurcation grafts placed with standard vascular surgical techniques. One patient received dextran 40 (50 ml/hour) for 48 hours postoperatively. The other subjects received no anticoagulants or platelet inhibitory drugs (including aspirin, dipyridamole, sulfinpyrazone, ibuprofen, and other nonsteroidal anti-inflammatory agents) during the period of study. No patient had clinically apparent peripheral emboli or graft occlusion during follow-up study.

All 8 subjects were initially studied 1 to 2 weeks postoperatively. Five subjects returned for repeat studies a mean of 31

weeks (range 28 to 34) and again at 55 weeks (range 50 to 62). Three patients were not restudied: 1 refused, 1 moved, and 1 could not be located. This study was approved by the University of Washington Human Subjects Review Committee. All subjects gave informed consent.

Platelet labeling, imaging and analysis: Autologous platelets were labeled with indium-111 oxine using a closed blood bag modification of the technique of Thakur et al[19] as previously described.[20] The initial centrifugation (350 g × 15 minutes) and subsequent centrifugations (1,300 g × 15 minutes) have been changed since the original description. The mean labeling efficiency for all 18 studies was 34 ± 10% (±1 standard deviation), which is lower than that reported in studies using open test-tube labeling methods,[19,21] presumably due to loss of the label in the interstices of the plastic blood bags. The mean injected dose did not significantly differ between the 3 serial study times (352 ± 33, 339 ± 33, and 257 ± 177 μCi, respectively). For all 18 studies, the mean percentage of indium-111 activity free in the plasma at 24, 48, 72, and 96 hours after labeled platelet injection was 5 ± 4%, 4 ± 2%, 6 ± 2% and 9 ± 4%, respectively.

The graft was imaged by taking an anterior view of the lower abdomen that largely excluded the liver and spleen for 150,000 counts, typically at 24, 48, 72, and 96 hours after labeled platelet injection.[14] Imaging was discontinued at 72 hours in 5 studies (4 initial studies and 1 at 55 weeks) and at 96 hours in 13. Images were recorded on Polaroid® trilens film for visual assessment of the unprocessed data and on a computer disc system with a 128 × 128 matrix to allow quantitation of platelet deposition. Qualitative visual analysis of the unprocessed images from all 18 graft studies, in addition to 12 previous studies from normal subjects without grafts,[14] was performed by 2 observers who were unaware of the clinical data or the study sequence. Images were defined as showing platelet deposition if there was one or more areas of activity present in the region of an aortic bifurcation graft that was clearly greater than the large vessel blood pool activity present above or below the area encompassed by a graft. Studies were graded as positive, negative, or equivocal for platelet deposition. On serial studies, a decrease in platelet deposition was defined as conversion of a positive study to either negative or equivocal.

Quantitative analysis of the platelet image data was performed using a graft/blood ratio that compared activity in the graft region to well-counted whole blood indium-111 platelet activity.[14] This ratio was determined for each patient at each imaging time. In 2 studies (both in the same patient studied at 2 and 34 weeks after graft implantation), graft/blood ratios could not be calculated because the patient refused to have serial venipunctures to obtain whole blood samples (2-week study) and because of a computer malfunction (34-week study). For purposes of comparison, the graft/blood ratios of young normal subjects without grafts are also presented; the data in normal subjects has been previously reported.[14] Statistical analysis was by paired or unpaired t testing. All values are expressed as mean ± standard deviation.

Results

Quantitative analysis (graft/blood ratio): As shown in Table I, there was a decline in the graft/blood ratios at the 24, 48, 72 and 96-hour imaging times from the initial to late studies. Among the 4 subjects who had 72-hour graft/blood ratios obtained at all 3 study times, the decrease from the early to middle to late studies was from 4.9 ± 2.2 to 3.3 ± 2.1 ($p = 0.07$) to 2.9 ± 2.0 ($p = 0.01$). Additionally, the mean of all graft/blood ratios obtained at all serial imaging times (24, 48, 72, and 96 hours) significantly decreased from the first study (4.4 ± 2.1) to the second study (3.0 ± 1.8, $p = 0.002$), implying a decrease in deposition. There was no further significant decrease from the second to the third study (2.8 ± 2.0) ($p = 0.001$ versus Study 1) (Fig. 1). For comparison, normal subjects had a mean value of 1.8 ± 0.7 for all graft/blood ratios. All patients with grafts had a decrease in the graft/blood ratio of at least one third

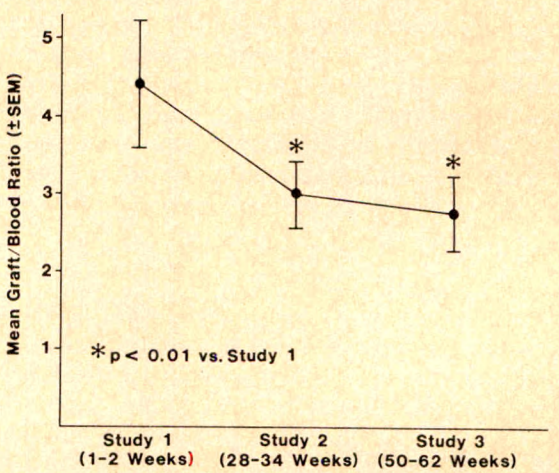

FIGURE 1. Platelet deposition on Dacron grafts in the first year after implantation. The mean of all graft/blood ratios (24, 48, 72, and 96 hours) significantly decreased from Study 1 to Study 2 ($p = 0.002$). There was no further significant decrease from Study 2 to Study 3. These results imply a decrease in deposition within the first 31 weeks after implantation.

TABLE I Graft/Blood Ratios

	Hours			
	24	48	72	96
Study 1 (1–2 weeks)				
All patients	2.4 ± 1.1	3.2 ± 1.3*	4.3 ± 2.2*	5.6 ± 3.5*
Patients with serial studies	3.0 ± 1.1	4.1 ± 1.3*	4.9 ± 2.2*	7.0 ± 3.5*
Study 2 (28 to 34 wk)	2.1 ± 0.8	2.3 ± 1.3	3.3 ± 2.1	3.5 ± 2.2*

TABLE II Visual Results

Case	Study 1 (1 to 2 wk)	Study 2 (28 to 34 wk)	Study 3 (50 to 62 wk)
1	+	EQ	−
2	+	+	EQ
3	+	+	+
4	+	+	+
5	+	+	+
6	+	ND	ND
7	+	ND	ND
8	−	ND	ND

+ = positive study; − = negative study; EQ = equivocal study; ND = not done.

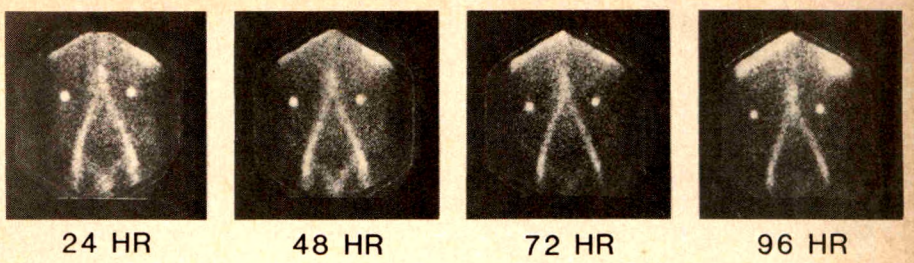

FIGURE 2. Diffuse platelet deposition is present throughout this Dacron aortic bifurcation graft 2 weeks after implantation. From 24 to 96 hours after labeled platelet injection, background blood pool activity decreases due to platelet senescence, while graft area activity remains intense.

on either the 72- or 96-hour image from the initial to the final study. However, despite the decline in the mean graft/blood ratio, patients with 1-year-old grafts continued to have a higher mean ratio than normal subjects ($p = 0.003$).

Visual analysis (Table II): On visual analysis, none of the 12 normal subjects had abnormal platelet deposition. In contrast, 7 of the 8 patients with grafts had detectable platelet deposition 1 to 2 weeks after surgery (Table II). All 5 patients who had serial studies had a positive result on initial study (Fig. 2). Of the 5 subjects studied at 31 ± 3 weeks and at 55 ± 5 weeks, results in 3 remained positive at both late studies. Of the other 2 subjects studied serially, 1 had only equivocal deposition at 28 weeks and no detectable deposition at 50 weeks and the other had a persistently positive study at 34 weeks but an equivocal study at 51 weeks (Fig. 3). Thus, 2 of 5 subjects had a visually detectable decrease in deposition at late study periods, although at both late studies, 4 of 5 subjects still had positive or equivocal images.

Discussion

This study documents that platelet deposition on Dacron grafts in humans is detectable in the early period after graft implantation and remains detectable in most patients studied 1 year later. Qualitative visual analysis detected deposition in 7 of 8 grafts studied 1 to 2 weeks after implantation and in 4 of 5 (3 positive and 1 equivocal) studied at 1 year. The visual results early postoperatively are similar to previous reports in which visually detectable deposition was present in recently implanted Dacron extracardiac conduits[22] and in recently implanted Dacron aortic bifurcation grafts.[18,21] The visual results at 1 year confirm our earlier findings of platelet deposition in 13 of 15 chronically implanted Dacron grafts.[14] It thus appears that most Dacron grafts in human subjects have detectable platelet deposition for long periods of time after implantation.

Whereas the qualitative visual data suggested that deposition diminished over time in 2 of the 5 subjects studied serially, the quantitative analysis suggested that deposition diminished in all subjects. Most, if not all, of the decrease in deposition occurred within the first 31 weeks after implantation; the graft/blood ratio did not significantly decrease further from the 31-week study to the 55-week study. These results are in agreement with those reported by Goldman et al[17,18] in similar groups of patients. They also found that deposition remained readily detectable at late study but that the rate of platelet accumulation diminished from early postoperatively to 6 to 12 months later. Their quantitative method assessed only the rate of platelet deposition determined over an 8-day period from limited regions of the graft, and thus their results are not strictly comparable to ours, which allow comparison of both the magnitude of deposition throughout the entire graft as well as the rate of deposition from 1 study to another. Our study documents a decrease in both the rate and magnitude of platelet deposition in the first year after implantation.

The finding of decreased platelet deposition over time is consistent with platelet survival studies. Platelet survival, which was not measured in the current study, has been found to be reduced in the first several months after placement of an arterial graft, but normalizes by 9 months to 1 year after implantation.[3,13] An increase in platelet survival would not affect our quantitative results because such an increase would equally affect both the numerator and the denominator of the graft/blood ratio and, thus, result in no change in this measurement of graft platelet deposition. Our findings document that the normalization of platelet survival that occurs in patients with grafts does not indicate cessation of platelet accumulation on the graft, because deposition remained detectable by both visual and quantitative analysis. Platelet imaging, by analyzing a specific localized site of platelet deposition, may be more sensitive for the detection of platelet accumulation than the platelet survival time, which reflects the entire circulating platelet pool.

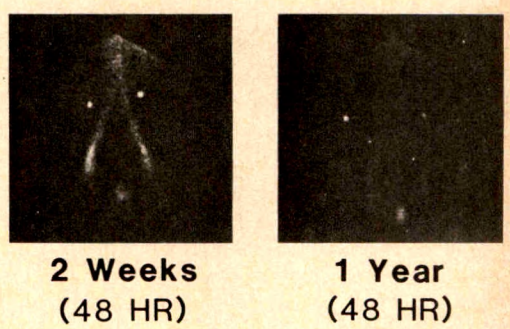

FIGURE 3. Diffuse platelet deposition was present in this Dacron aortic bifurcation graft 2 weeks after implantation (**left**) but was not detectable 1 year later (**right**). Both images were obtained 48 hours after labeled platelet injection.

The increase in the mean graft/blood ratio from 24 hours to 96 hours in both early and late postoperative studies implies progressive deposition of labeled platelets or labeled platelet products on the prosthetic flow surface over a 4-day period. Eventually, an equilibrium must be reached between platelet deposition and removal. Our data indicate that such a steady state is not reached in the first 96 hours after labeled platelet injection. These results confirm our earlier findings in 15 patients with chronically implanted Dacron grafts[14] and findings in a baboon model of implanted Dacron prostheses.[1]

It is possible that our results at the initial study would have been more dramatic had patients been labeled earlier postoperatively, because the peak platelet deposition rate may occur very shortly after graft implantation. The initial studies were done at 1 to 2 weeks because patients were clinically stable at that time and because active bleeding into the operative site, which would invalidate the results, could be excluded.

Detectable platelet deposition on Dacron-blood interfaces implies incomplete or ineffective graft endothelial cell coverage. Our findings of deposition on acute and chronic grafts are consistent with the limited data regarding the histology of grafts implanted in human subjects. These studies have rarely documented endothelial cell coverage[8,23–29]; however, the same studies for the most part did not note significant platelet deposition, and it is possible that the fixation techniques required to preserve platelet and endothelial cell morphology were inadequate. Data in human subjects contrast with animal studies in which endothelial cell coverage of the graft flow surface and decreasing platelet deposition occur over time.[2,3,5–12] This apparent disparity between the human and animal response to prosthetic materials suggests that studies of prosthetic materials in animals should be extrapolated to human beings only with caution.

Berger and Salzman[30] noted that inadequate measures for assessing the thrombogenicity of prosthetic materials in patients have impeded the development of improved materials. Platelet imaging, which is noninvasive, repeatable, organ specific and quantifiable, may provide an additional means of assessing prosthetic thrombogenicity in man. Less reactive prosthetic materials should lead to a visual and quantifiable decrease in platelet deposition both initially and on longitudinal study. In addition, as has been suggested in animal models, platelet imaging may be helpful in assessing whether platelet inhibitory or anticoagulant drugs can decrease thrombus formation on prosthetic surfaces.

This study demonstrated consistent early platelet deposition on Dacron grafts in human beings. Although deposition decreases over 31 weeks, it remains readily detectable in most patients at 1 year. These findings suggest absent or incomplete endothelial coverage of Dacron graft flow surfaces in human subjects in the first year after implantation.

Acknowledgments: We acknowledge the excellent technical assistance of Kathy W. McFadden, Michael Simmons and John B. Martin. We thank Susan Murphy, Patricia Jenkins and Maxine Cormier for preparation of the manuscript.

The third issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

Cardiology 1983

What is CARDIOLOGY 1983?

- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1983 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

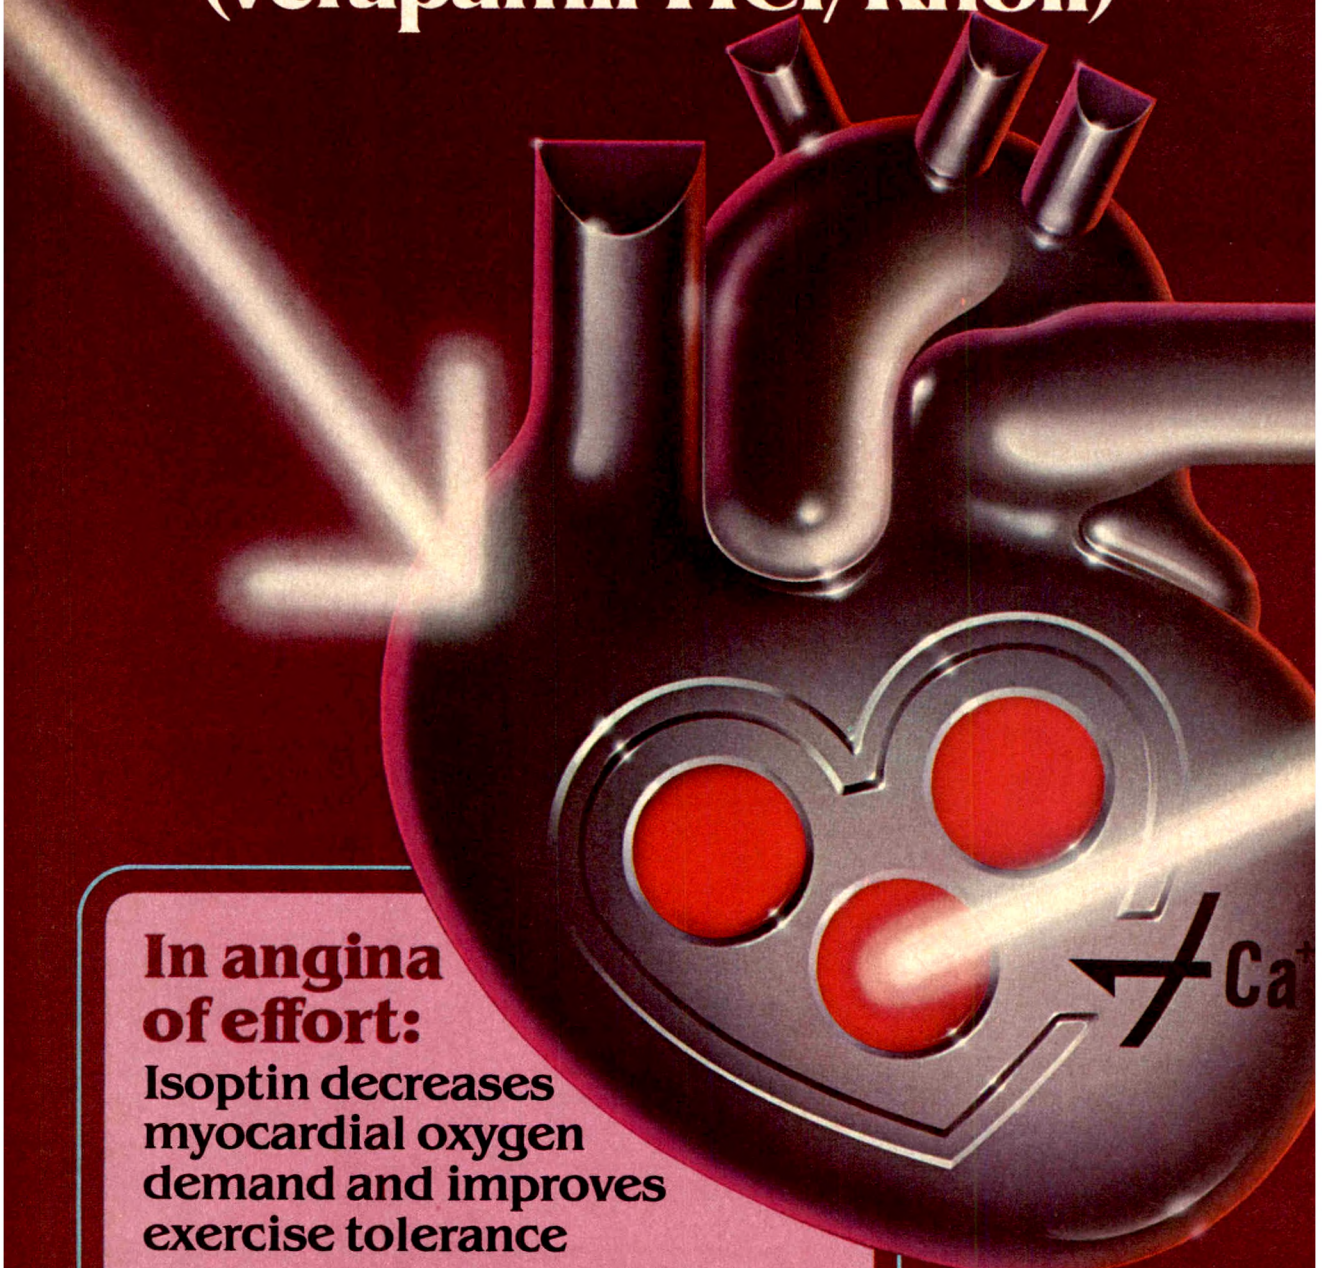
ISOPTIN TABLETS
(verapamil HCl/Knoll)



In angina of effort:

Isoptin decreases myocardial oxygen demand and improves exercise tolerance

By decreasing peripheral vascular resistance and cardiac afterload, Isoptin decreases the workload of the heart and the amount of oxygen consumed by heart muscle. So angina patients on Isoptin are able to exercise significantly longer without pain — from 47% to 67% longer in three well-controlled studies.[1-3]

An agent with two major antianginal actions

In angina at rest:

Isoptin dilates the coronary arteries and prevents coronary vasospasm

While beta blockers may cause coronary vasoconstriction, Isoptin prevents spasm and dilates both normal and atherosclerotic coronary arteries. In a well-controlled comparative study of patients with unstable angina at rest, propranolol did not differ significantly from placebo, while Isoptin reduced nitroglycerin requirements by 84% and the incidence of transient ischemic ECG events by 81%.[4]

Why Isoptin?

Isoptin is an effective first-line agent for patients with angina of effort, angina at rest, or mixed angina, in which both spasm and obstruction may be present.[5,6]

Unlike certain vasodilators and unlike the beta blockers, Isoptin achieves its antianginal effects with minimal effect on heart rate. Patients on Isoptin do not experience any vasodilation-induced, reflex increases in heart rate. And, in patients in whom propranolol 320 mg/day decreased the heart rate 18 to 20 beats/minute, Isoptin 480 mg/day decreased it only 4 to 9 beats/minute.[1,7] Isoptin requires no special caution in patients with asthma, COPD, diabetes, or peripheral vascular disease.

Isoptin is contraindicated in severe left ventricular dysfunction, sick sinus syndrome (except in patients with a functioning artificial ventricular pacemaker), hypotension or cardiogenic shock, and second- or third-degree AV block.

Please see accompanying page for brief summary of prescribing information.

ISOPTIN® TABLETS
(verapamil HCl/Knoll)
80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** ISOPTIN should be avoided in patients with severe left ventricular dysfunction (e.g., ejection fraction <30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before ISOPTIN is used. ISOPTIN may occasionally produce hypotension (usually asymptomatic, orthostatic, mild, and controlled by decrease in ISOPTIN dose). Occasional elevations of liver enzymes have been reported; patients receiving ISOPTIN should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (e.g., W-P-W or L-G-L syndromes) may develop a very rapid ventricular response after receiving ISOPTIN (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema, and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with ISOPTIN. **Precautions:** ISOPTIN should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of ISOPTIN and beta blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, ISOPTIN should be used alone, if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with ISOPTIN and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic ISOPTIN treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when ISOPTIN is given, and the patient carefully monitored. ISOPTIN may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after ISOPTIN administration. Until further data are obtained, combined ISOPTIN and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. *Pregnancy Category C:* There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during ISOPTIN use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, maculae, and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** ISOPTIN (verapamil HCl) is supplied in 80 mg and 120 mg sugar-coated tablets. July 1982 2068

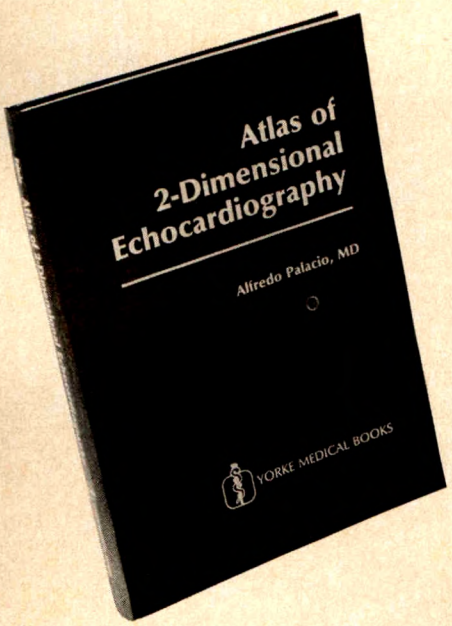
The First Practical Atlas of 2-D Echocardiography Ever Published



A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms

Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School;
Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $65.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

quantum
Model 253-19
Intermedics Inc.
FREEPORT, TEXAS
VOO VVI VVT

QUANTUM™

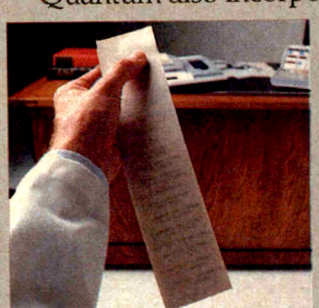
The World's Only Pacemaker Within A Pacemaker.

The smallest multi-programmable pacemaker providing the only true margin of safety for your patients.

Intermedics' Quantum unipolar 253-19 pacemaker has *two completely independent* circuitry systems to perform critical functions in

the event, however unlikely, of a circuit or component failure. Truly, peace of mind pacing. And it's only 8mm thin.

Quantum also incorporates Inter-Lock,™ the



lead connector system for easier handling at implant without the problems of loose screws or caps.

Yet with all these advantages, Quantum provides the advanced measured telemetry, full multi-programmability and trans-telephonic capabilities that you have come to depend on.

With its back up system, Quantum from Intermedics brings pacing yet another technical step forward. For more information about the only pacemaker with its own built-in pacemaker, contact your nearest Intermedics representative or call us, toll-free at 1-800-231-2330 (in Texas dial 1-800-392-3726).

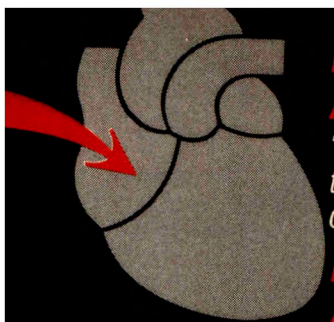
QUANTUM INDICATIONS AND CONTRAINDICATIONS

The indications for cardiac pacing are increasing as pacemakers become more sophisticated and as advanced methods for patient management become more widespread. Generally accepted indications for long-term cardiac pacing include, but are not limited to: (1) sick sinus syndrome; (2) chronic, symptomatic drug-resistant sinus arrhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) block as seen in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bundle branch block; and (7) hypersensitive carotid sinus syndrome (carotid sinus syncope). In addition, certain patients presenting such symptoms as intractable, recurrent arrhythmias, and who have been shown to benefit from temporary cardiac pacing, are considered candidates for permanent cardiac pacing.

The indications for permanent pacing in cases of acute myocardial infarction have not yet been rigorously defined. Factors to be considered include the location of the myocardial infarct, the presence or absence of symptoms, ventricular rate, the mechanism of the arrhythmias, and response to therapy. In general, symptomatic drug-resistant bradyarrhythmias that impair cardiac output are considered indications for pacing in patients with acute myocardial infarction, regardless of infarct location.

There are no know contraindications to the use of pacemakers as a medical method for control of heart rate.



IN SUPRAVENTRICULAR ARRHYTHMIAS:

"Quinidine remains the drug of choice to prevent recurrence of atrial fibrillation or flutter."[1]

IN VENTRICULAR ARRHYTHMIAS:

"Quinidine is one of the most useful drugs for chronic treatment of ventricular arrhythmias . . . or for the prevention of ventricular fibrillation."[2]

(quinidine gluconate)
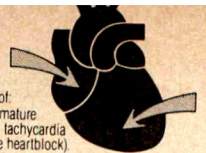
DURA-TABS®



INDICATIONS AND USAGE:
Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:
1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).
2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).
CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.
2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.
3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.
4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.
5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.
7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.
8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.

Drug Interactions: *Drug*	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.
Less frequently encountered adverse reactions:
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.
See package insert for full information.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Systematic Analysis of Contrast Echocardiograms

RICHARD S. MELTZER, MD, ZVI VERED, MD, JOS ROELANDT, MD, and HENRY N. NEUFELD, MD

Contrast echocardiography was first described in 1968. Since then, many reports have described clinical and experimental uses for the technique. Contrast echocardiography is performed at least occasionally in most echocardiography laboratories, but most physicians use this technique merely to determine the presence of a shunt or, more rarely, for structure identification. Contrast echocardiography can provide much more information. Some different types of information available from con echocardiographic records are discussed, inclu timing of contrast appearance within the ca cycle, relative timing of appearance in diff cardiac structures, relative intensity of con opacification, cyclical changes in contrast op cation, negative contrast effect, slope of con trajectories on M-mode contrast echocardiogra and clearance times.

In 1968, Gramiak and Shah[1] first reported the contrast echocardiographic effect achieved by injecting idocyanine green contrast material in the heart during echocardiography. They credited Joyner as the discoverer of the effect. Since then, the literature on contrast echocardiography has grown and the subject has been extensively reviewed.[2–11] Although most echocardiographic laboratories use contrast echocardiography at least occasionally,[12] there is room for further organized thinking about systematic analysis of contrast echocardiograms to maximize their diagnostic potential, in a manner analogous to systematic inspection of a chest X-ray or M-mode echocardiogram to insure that a maximum of diagnostic information is obtained from the study. Some physicians are unaware of the amount and type of information inherent in a contrast echocardiogram. This report points out the types of information available from systematic analysis of contrast echocardiograms.

Timing of Onset of Contrast Appearance

With respect to the cardiac cycle: Contrast material frequently enters an echocardiogram fairly suddenly, within a small fraction of a cardiac cycle. The timing of this entry may be reproducible even if the peripheral intravenous injection technique is quite variable. This phenomenon is used diagnostica detect tricuspid regurgitation when imaging the in vena cava (IVC) echocardiographically.[13–15] If th rograde flow of contrast material enters the IVC sl after atrial contraction, tricuspid regurgitation i likely. Tricuspid regurgitation is diagnosed if it e the IVC shortly after the onset of the v-wave on the atrial pressure tracing (or jugular or IVC pulsati

Atrial septal defect (ASD) is usually distingu from ventricular septal defect (VSD) on cor echocardiography by the position and direction abnormal contrast flow. There are also some more s differences of timing of contrast appearance. In contrast material enters the left ventricle in dia after the mitral valve has been opened. Caref spection of contrast echocardiograms will demon that the first appearance of contrast material in th ventricle across an uncomplicated VSD is earlier, d ventricular relaxation before the mitral valve o because this is when a small right-to-left gradient in a predominantly left-to-right shunting VSD.[16] I timing the entry of contrast material into the lef tricle after peripheral intravenous injection has proposed[17] as a method of roughly quantifying th modynamics across a VSD: patients with pressu the right ventricle <60% of left ventricular pre usually do not have contrast echocardiographic s ing unless ventricular premature contractions Those with right ventricular pressure in the range to 80% of left ventricular pressure and a pulmo systemic flow ratio (Q_p/Q_s) from 2.0 to 5.0 had ap ance of the left ventricular contrast material d relaxation, but the contrast material returned t right ventricle during mid- and late diastole, s

none remained in the left ventricle at the onset of systole and thus none was ejected into the aorta (Fig. 1). A third pattern was found in patients with systemic right ventricular pressures and a Q_p/Q_s >3:1. In these patients, contrast material initially appeared in the left ventricle at the same time in the cardiac cycle as in the previous group, but it remained in the left ventricle through systole and was ejected into the aorta. A fourth pattern was found in patients with significant pulmonary stenosis, systemic right ventricular pressures, right-to-left shunting, and a Q_p/Q_s ranging from 0.4 to 0.8. The appearance time of contrast material in the left ventricle was distinctly earlier in the cardiac cycle than for the previous group. As in the previous group, the contrast material remained in the left ventricle throughout diastole and was ejected into the aorta on the next systole. A fifth pattern was found in 3 patients with Eisenmenger physiology and pulmonary vascular resistance >15 U/m^3. In these patients, entry of contrast material into the left ventricle was still earlier in the cardiac cycle than that in patients in the third and fourth group. The investigators concluded that timing of contrast entry into the left ventricle after peripheral intravenous injection yields important information about the hemodynamics and shunting across a VSD.

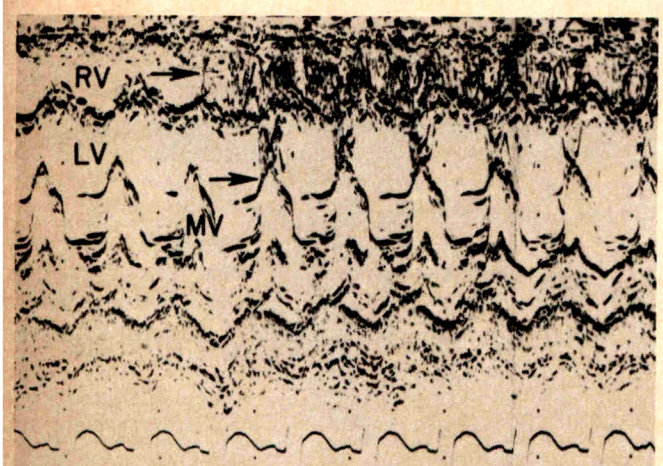

FIGURE 1. Echocardiographic study from a patient with a right ventricular/left ventricular pressure ratio of 0.7. The initial appearance of contrast within the right ventricle (RV) is indicated by the **upper arrow.** The appearance of contrast anterior to the mitral valve (MV) in the LV is indicated by the **lower arrow.** During late ventricular filling, contrast returns completely to the RV, with none persisting in the LV during ventricular systole. (Reproduced, by permission, from the American Heart Association.[17])

With respect to different cardiac chambers: In ASD, contrast material injected into a peripheral vein is first seen in the right heart and then crosses into the left heart within the following 1 to 3 cycles. If contrast material is first imaged in the left heart 10 to 12 cardiac cycles after entry into the right heart, intrapulmonary rather than intracardiac shunting is suggested.[18] This delay ranges from 0 to 5 cardiac cycles (mean 1.5) in patients with ASD and from 2.5 to 10 cardiac cycles in patients with pulmonary arteriovenous fistula.[19] Thus, patients with intracardiac shunting can usually be distinguished from those with intrapulmonary shunting on the basis of the relative timing of arrival of contrast material in the left heart, although there may be an overlap between the 2 groups for a relative arrival delay of about 3 to 5 cardiac cycles (Fig. 2).

The sequence of opacification of the cardiac chambers and great vessels provides information on intracardiac flow similar to that available from angiographic or radionuclide studies, but unavailable by other echocardiographic means including Doppler echocardiography.

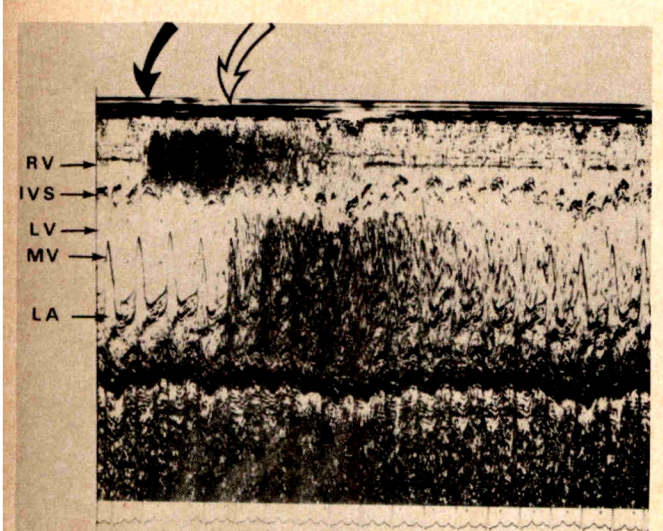

FIGURE 2. Contrast echocardiogram after intravenous injection in a patient with a pulmonary arteriovenous fistula. Initial opacification of the right ventricle (RV) is indicated by the **upper solid arrow.** Opacification of the left atrium (LA) and left ventricle (LV) 3 cardiac cycles later is shown by the **open arrow.** IVS = intraventricular septum; MV = mitral valve.

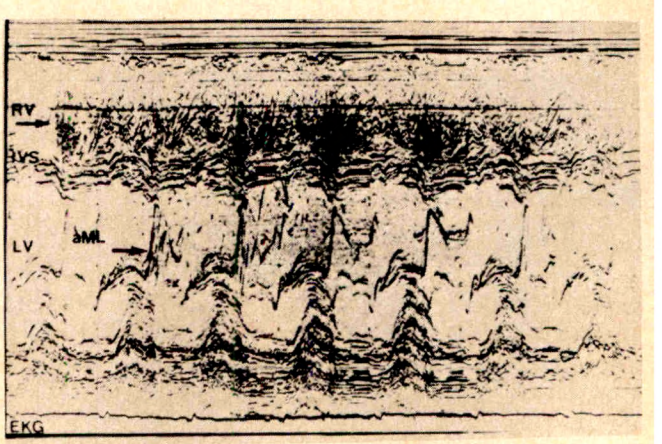

FIGURE 3. M-mode echocardiogram after peripheral venous injection of 5% dextrose in a patient with atrial septal defect. During the fourth and fifth diastoles in the tracing, the contrast is relatively more intense in the right ventricle (RV) and less intense in the left ventricle (LV) than in the beats immediately before and after. The reason is a lessening of the right-to-left shunt during inspiration. aML = anterior mitral leaflet; EKG = electrocardiogram; IVS = intraventricular septum.

This information is particularly important in complex congenital heart disease.[4,20,21]

Relative Intensity of Contrast Opacification

Frequently, different cardiac chambers opacify to a markedly different extent. Echocardiographers soon realized that relative opacification did not convey information about the size of an ASD, but this concept is misleading. It would be unreasonable to expect useful diagnostic information on the size of a left-to-right shunt by looking at the magnitude or timing of right-to-left shunting,[22] and this is why left-sided cardiac opacification after intravenous injection conveys no information about the significance of most ASDs (without pulmonary hypertension). However, the relative intensity of contrast opacification is a rough guide to the degree of relative filling in the direction of the shunting; that is, most patients with ASD show greater relative contrast opacification of the right ventricle compared with the left ventricle because flow from the contrast-filled right atrium preferentially enters the right ventricle rather than the left atrium. When pulmonary hypertension and Eisenmenger physiology occur, this situation changes and the equal intensity of left-sided cardiac opacification relative to the right heart suggests this diagnosis.

Occasionally the negative contrast effect of unopacified blood entering the right atrium from the left atrium is quite striking. However, considerable experience is necessary to reliably distinguish a negative contrast effect due to abnormal flow across an ASD from the normal inferior vena cava and coronary sinus flow. In our experience, a negative contrast effect is not a sensitive sign, either.

Figure 3 is an example of how relative contrast density can give clues to underlying physiologic phenomena. This M-mode echocardiogram was taken after peripheral intravenous contrast injection in a patient with ASD. During inspiration, the relative contrast density is greater on the right side and less on the left, indicating a decrease of right-to-left shunting at this phase of the respiratory cycle.

In patients with complex congenital disease, the great vessel receiving most of the systemic venous return can be identified as the one with the relatively greater opacification after intravenous injection. This important use of relative intensity is quite helpful in the analysis of patients with transposition of the great arteries: although the anteroposterior relations of the great arteries in this group of patients are quite variable from the precordial transducer position, on suprasternal studies the superior great vessel (closer to the transducer) is the aorta. Therefore, if the relative intensity in this vessel is greater than that in the pulmonary artery below it, the echocardiographer can deduce that most of the systemic venous return is reaching the aorta, suggesting the presence of transposition with insufficient intracardiac mixing of pulmonary and systemic venous return.[23] This situation should change toward a more equal relative contrast intensity after successful Rashkind balloon atrial septostomy.

Clearance Time

It is easier to define the concept of clearance time theoretically than to apply the definition practically. Clearance time is the length of time or number of cardiac cycles necessary for contrast material to be cleared from a particular cardiac chamber or great vessel after its initial appearance. The problem in application of this definition is that the end point is not well defined: contrast decays exponentially in most situations, and exactly where to place the end is frequently difficult. There are 2 approaches to arbitrarily aid in clinical research using clearance times: (1) Take the last cardiac cycle where an arbitrary number—perhaps 5—of definite contrast images is seen as the end point. (2) Sidestep the problem of definition of an exact end point entirely by statements such as, "Contrast remained in the chamber >20 cardiac cycles," or "All normal subjects showed clearing of contrast in <10 cardiac cycles." Another problem with using clearance time clinically is the lack of reproducibility in contrast echocardiographic injections; an injection with more intense contrast or slower contrast delivery may also take longer to clear than one with a smaller contrast bolus.

Both low cardiac output and regurgitation of a valve immediately proximal or distal to a chamber or vessel would be expected to increase the clearance time of contrast material within that chamber or vessel. Clearance time has been reported prolonged in 1 clinical example of each: Tsuyuguchi et al[24] recently suggested that prolonged clearance time of contrast in the right ventricle indicates right-sided heart failure, and it has been suggested that tricuspid regurgitation is severe when clearance time of contrast material in the inferior vena cava after upper extremity intravenous injection exceeds 20 cardiac cycles (S. Castellanos, MD, Athens, Greece, personal communication).

Another use of clearance time is to examine the relative clearance time of 2 different cardiac chambers or vessels. In transposition of the great arteries, the aorta receives most of the systemic venous return and is thus opacified more intensely and persistently than the pulmonary artery after an intravenous contrast injection. Hunter and Sutherland[25] state that when there is minimal interatrial mixing and aortic saturation is <40%, the aorta is opacified more than twice as many cycles as the pulmonary artery. As mixing improves at the atrial level and the aortic saturation is 40 to 60%, the pulmonary artery opacifies more than half as many cycles as the aorta, although there is usually still differential opacification. When mixing is adequate and aortic saturation is >60%, both great arteries have similar contrast clearance times; if the clearance times cannot be distinguished at all, there is usually <10% difference in aortic and pulmonary artery saturation.

Videodensity Analysis

A proposed method to quantify contrast appearance and clearance on 2-dimensional echocardiography is to examine the videodensity decay from a selected cham-

ber or vessel. This method has been reported capable of quantifying cardiac output[26] and shunts in the direction of contrast flow ("positive" contrast rather than "negative" contrast).[27,28] We have found variability of videodensity decay constants to be an important problem[29] and look to the availability of a more reproducible contrast agent before this technique can attain clinical value.

Echocardiographic contrast can be used with 2-dimensional echocardiography to assess myocardial perfusion in experimental animals,[30,31] and videodensity determinations have been reported to correlate with measurement of myocardial blood flow by radioactive microspheres.[32]

Slope of Contrast Trajectories on M-Mode Echocardiograms

Assuming that microbubbles of air are the source of contrast,[33] the slope of an individual contrast trajectory on an M-mode tracing is the component of the velocity of that microbubble projected in the direction of the ultrasonic beam, toward or away from the transducer (Fig. 4). Both qualitative information (motion toward or away from the transducer depending on whether the slope is positive or negative, respectively) and quantitative information (the absolute value of this velocity in cm/s) are thus available from systematic analysis of contrast trajectory slopes. Using Doppler echocardiography as a reference, we[34] recently verified that the velocity measured from M-mode slopes closely correlates with the velocity measured from the Doppler shift in the pulmonary artery and across the tricuspid valve in a group of normal volunteers. In fact, there are many similarities between measuring velocities by Doppler or analyzing M-mode contrast slopes, mainly because they both measure the same component (along the ultrasonic beam) of the 3-dimensional velocity vector. Other similarities and relative advantages of each technique are listed in Table I. Shiina et al[35] recently showed that M-mode contrast slopes correlate with invasive measurements of blood velocity across the tricuspid valve and pulmonary artery, and that velocities measured from contrast slopes change as expected with simple interventions. Valdes-Cruz et al[36] have cautioned that microbubble velocity is not necessarily the same as blood velocity.

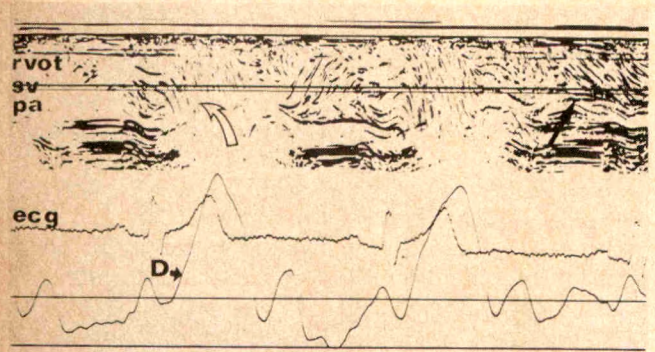

FIGURE 4. M-mode echocardiogram (**upper tracing**) of the right ventricular outflow tract (rvot) and pulmonary artery (pa) after peripheral intravenous contrast injection. The simultaneous mean Doppler velocity signal (D, **lower tracing**) is sampled at sample depth (sv) on the M-mode tracing. The Doppler tracing is inverted so that velocities away from the transducer are portrayed as positive deflections. Higher velocities away from the transducer are seen during systole (**open arrow**) both as steeper contrast slopes and as a higher Doppler velocity. During diastole (**closed arrow** on right) the slope of contrast in the sv approaches 0, as does the Doppler signal. ecg = electrocardiogram.

TABLE I Echocardiographic Velocity Measurements: Doppler Versus M-Mode Contrast Slope

Similarities
Both look at the component of blood velocity along the echocardiographic beam direction (towards or away from the transducer)
The same transducer may be used for both studies
Advantages of M-mode contrast echocardiography
Not limited by distance from target or maximum velocity that can be detected
Samples many depths simultaneously (only multigate or continuous wave Doppler instruments do this)
Uses less expensive, more generally available equipment (only M-mode instrument and intravenous line needed)
Advantages of Doppler echocardiography
Entirely noninvasive
Can sample left heart velocities in absence of shunt
More clinical experience available with this technique than with M-mode slope analysis
Measures blood velocity rather than microbubble velocity

Because velocity analysis from M-mode contrast slopes is newly reported, there are as yet few clinical studies using this technique. Those already reported are largely qualitative, using direction toward or away from the transducer to diagnose flow abnormalities on the right side of the heart in pulmonary regurgitation[37] and pulmonary hypertension.[37,38] An example of the use of contrast echocardiography to diagnose pulmonary insufficiency is shown in Figure 5. Although it is too early to determine if quantitative velocity measurements from contrast slopes have clinical utility, the rapid growth of Doppler echocardiography suggests that velocity measurements provide valuable clinical information.

Other Clues From Contrast Echocardiograms

Cyclical opacification and clearing of the pulmonary artery after intravenous injection, viewed by suprasternal M-mode echocardiography, suggest patent ductus arteriosus.[23] The same phenomenon should be seen in aortopulmonary window, because the physiology is similar. The phenomenon is seen because during systole, contrast-containing blood is ejected from the right ventricle into the pulmonary artery, and in diastole the pulmonary artery receives contrast-free blood from the aorta through the ductus. Cyclical opacification of the IVC can be seen both in patients with tricuspid regurgitation (during the v wave) and in normal subjects (during the a wave), as mentioned. After peripheral intravenous injection in most normal subjects, cyclical variation can be seen in the intensity, direction, and velocity of contrast opacification across the tricuspid valve, in the right ventricular outflow tract, and across the pulmonary valve.

Contrast echocardiography is the only method that can follow the flow pattern of individual "particles" (in this case, microbubbles) through the heart. It is thus well suited to the analysis of vortexes, "streaming," and other abnormal flow patterns. Streaming refers to lack of complete mixing of blood in a chamber, so that blood from a certain origin proximal to that chamber preferentially flows to one or more specific distal destinations. This pattern is frequently seen in the right ventricle after intravenous injection.

Problems and Limitations

The most frustrating problem with contrast echocardiography is that it is not consistent and reproducible: An injection may produce excellent contrast and the following one with seemingly similar technique may yield little contrast. Furthermore, there is no guarantee that microbubbles in the circulation travel with exactly the same velocity as the surrounding blood stream. Their distribution across a vessel does not need to be uniform; they might preferentially gather in the area of lower velocity along the vessel wall or in the central stream of maximal velocity. Another possibility is that bubbles of different size have different behavior and that different populations preferentially seek the wall or the central stream. Although commercial microbubble contrast agents may alleviate some of these problems, it is unlikely to solve all of them. Awareness of methods that may increase the yield of contrast using "standard" agents,[39] or the addition of a small amount of medically pure carbon dioxide[40] can improve the yield of satisfactory contrast studies.

Intense contrast can "overload" the instrumentation in 1 of several distinct ways. Returning echoes can become too intense for normal processing by the instrument set for processing of echoes in the absence of contrast. This is especially true when Doppler echocardiography is being used. Ultrasound travels slower in air than in water and slower in the air-water medium of a microbubble suspension than in normal blood. Thus, spurious contrast echoes may be displayed at locations further away from the transducer after the sound beam has passed an area of intense contrast. If this phenomenon is not well understood, the echocardiographer runs the risk of falsely diagnosing a shunt by contrast echocardiography. Further, intense contrast can reflect so much of the ultrasonic beam energy that not enough is left to image more distal structures during the period of maximum contrast intensity, and "drop-out" results in the distal image. Finally, the gray scale capacity of both M-mode and 2-dimensional echocardiography allows a far smaller range of output than the range of ultrasonic signals returning to the transducer. Thus "video-display overload" occurs when a pixel is at its maximum brightness and the increased ultrasonic signal due to more intense contrast cannot be displayed as a further increase in videointensity.

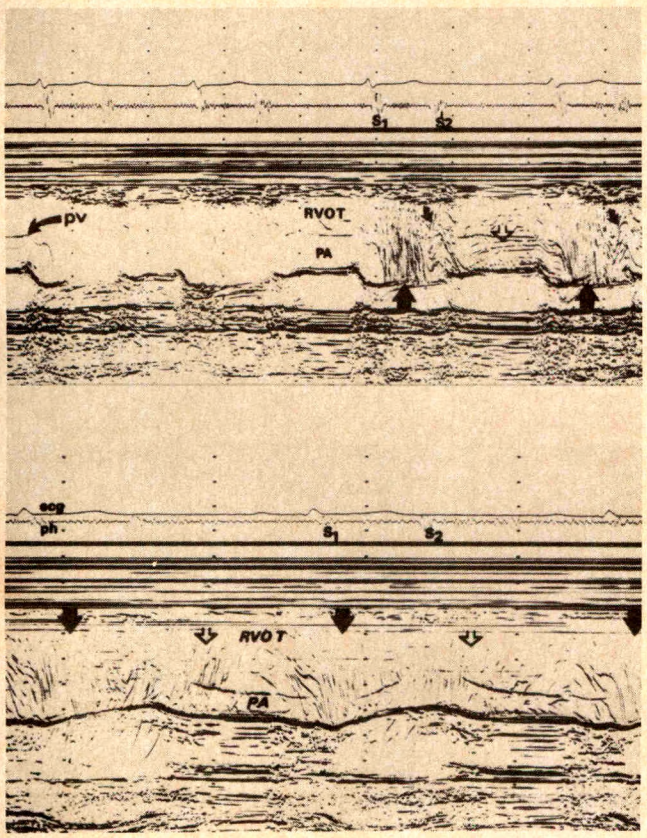

FIGURE 5. M-mode echocardiograms taken after peripheral intravenous dextrose injections with the echocardiographic transducer aimed in the right ventricular outflow tract (RVOT), pulmonary artery (PA) direction. **Upper panel,** in a normal patient, contrast material flows away from the transducer (anterograde) during systole (**heavy black arrows**). There is a short duration of retrograde flow toward the transducer coincident with S_2 (**short curved arrows**), and then no significant retrograde flow imaged during diastole (**open arrow**). **Lower panel,** in a patient with pulmonary insufficiency, contrast flows toward the transducer (that is, retrograde) throughout early diastole (**open arrows**).

Left Atrial Abnormality As an Electrocardiographic Criterion For the Diagnosis of Left Ventricular Hypertrophy in the Presence of Right Bundle Branch Block

MARVIN L. MURPHY, MD, P. NIHAL THENABADU, MD, NEIL de SOYZA, MBBS, JAMES E. DOHERTY, MD, and BONNIE J. BAKER, MD

Left atrial (LA) abnormality determined from precordial lead V_1 was assessed by 2 observers as a criterion of left ventricular (LV) hypertrophy in the presence of right bundle branch block (BBB) in 23 patients. The presence of LV hypertrophy was confirmed from a postmortem cardiac partition technique and defined at 2 levels of confidence: probable and definite hypertrophy. Observers reliably differentiated between the hypertrophied and normal-sized ventricle in the presence of right BBB by using LA abnormality as an electrocardiographic criterion. When defined as definite hypertrophy, observer 1 correctly identified LV hypertrophy in 78% of the cases and observer 2 in 67% of the cases. False-positive results were present in 21% of cases by observer 1 and 14% by observer 2. Comparable results were achieved when a definition of probable hypertrophy was used. Observer performance of recognition of LA abnormality in this study was satisfactory with 91% agreement between observers. Our results are comparable and in some instances superior to conventional criteria commonly recommended to diagnose LV hypertrophy on the electrocardiogram without right BBB.

Left atrial (LA) abnormality was carefully defined in the V_1 lead of the scalar electrocardiogram by Morris et al,[1] and was recognized as a marker of left ventricular (LV) hypertrophy in the development of electrocardiographic criteria.[2,3] Patients with a variety of cardiac disorders, including hypertension,[4] aortic stenosis,[5] and cardiomyopathies,[6] frequently exhibit the typical pattern of LA abnormality. In addition, Rios et al[7] found a high incidence of LA abnormality on electrocardiograms in patients with coronary heart disease and associated LV dysfunction. An elevated wedge pressure was observed in a majority of patients with LA abnormality studied by DiBianco et al,[8] indicating LV dysfunction, which is commonly associated with LV hypertrophy.

Left bundle branch block (BBB) on the electrocardiogram is associated with LV hypertrophy at autopsy in approximately 90% of cases.[9] In contrast, right BBB is not predictably associated with LV hypertrophy, and the usual electrocardiographic criteria recommended for LV hypertrophy may be unreliable in the presence of right BBB.[10,11] The criterion of LA abnormality compared with others may be used to advantage in the presence of right BBB. This autopsy study was designed to test the effectiveness of LA abnormality as an electrocardiographic criterion for detecting LV hypertrophy in patients with right BBB.

Methods

From 1966 to 1979, 3,202 autopsies were performed at the Little Rock Veterans Administration Medical Center. Of these, 513 (16%) had a special cardiac examination using the methods of Schlesinger[12] and Reiner et al.[13] The first method provides information on the extent of coronary artery obstruction and the second allows division of the heart into specific left and right ventricular masses excluding epicardial fat, vessels, and valvular structures. Of these 513 patients, 26 had right BBB on the electrocardiograms as usually defined.[14] Three of these patients had atrial fibrillation and were excluded, leaving 23 with right BBB. These 23 form the basis of this report.

All 23 patients had satisfactory electrocardiograms performed with usual care and standardization as recommended[15,16] and were recorded on either a single-channel Burdick

model EK-5 or a Hewlett-Packard 1511B electrocardiograph machine. Postmortem coronary angiograms were scored as previously described.[17] On the basis of data from a control population using cardiac partition techniques, the degree of hypertrophy was defined as probable in those with a LV weight >177 g and as definite if LV weight was >200 g as previously described.[17] Right ventricular hypertrophy was considered present when the weight was >65 g.[18] Patient records were reviewed for clinical data. The definitions of coronary, hypertensive, and valvular heart disease and obstructive pulmonary disease were as previously reported.[17,18] Congestive heart failure was considered present if diagnosed by the examining physician based on the usual criteria.

The electrocardiographic criterion of LA abnormality as defined by Morris et al[1] was used. These consisted of a P-wave terminal force ≥0.04 second in duration and ≥1.0 mm in negative amplitude. To assess interobserver variability, 2 observers independently interpreted the electrocardiograms for LA abnormality.

The following conventional criteria recommended for the electrocardiographic diagnosis of LV hypertrophy in the presence of right BBB were evaluated by 1 observer (MM): (1) Lewis index: net positivity in lead I plus net negativity in lead III ≥17 mm[19]; (2) Sokolow index: S in lead V_1 + R in lead V_5 or V_6 >35 mm[20]; (3) R in aVL >7.5 mm[21]; (4) intrinsicoid deflection in V_5 or V_6 ≥0.05 second[22]; (5) left axis deviation >−30°[22]; and (6) tall R waves in lateral precordial leads[14] arbitrarily defined as >15 mm in V_5 or V_6 by this study.

Results

All patients were men, with an average age of 70 ± 12 years (mean ± standard deviation [SD]). There were 17 patients with coronary heart disease; 2 had associated hypertensive disease and 3 had associated chronic obstructive pulmonary disease. Of the remaining 6 patients, 1 had both hypertensive and chronic obstructive pulmonary disease, 2 chronic obstructive pulmonary disease, 1 valvular aortic stenosis, 1 cardiomyopathy, and 1 no organic heart disease. Thirty-nine percent of patients had heart failure. The right ventricular weight for the 23 patients was 58 ± 21 g (mean ± SD). The LV weight for the 23 patients was 195 ± 68 g (mean ± SD). Of the 23 patients, 12 had a LV weight >177 g, qualifying for our definition of possible LV hypertrophy, and in these 12 the LV weight was 247 ± 52 g (mean ± SD). Nine patients had a LV weight >200 g, qualifying as definite LV hypertrophy, and in these 9 the LV weight was 265 ± 46 g (mean ± SD). Right ventricular hypertrophy was present in 5 of 9 patients whose LV weight was >200 g, in none of 3 patients with an LV weight of 177 to 200 g, and in 1 of 11 of those with normal LV weight.

The average time from electrocardiography to the patient's death was 3.7 weeks (range 0 to 28). However, 86% of the electrocardiograms selected were within 8 weeks of death.

The results of analysis for the presence of LA abnormality in 23 patients with right BBB are presented in Table I. Observer 1 correctly diagnosed LV hypertrophy in 75 to 78% of the cases, with a false-positive diagnosis in 18 to 21%; observer 2 diagnosed LV hypertrophy in 58 to 67% of the cases with a false-positive diagnosis in 9 to 14%. These results varied according to the anatomic definition of hypertrophy. Therefore, the recognition of LA abnormality was helpful in separating the normal from the hypertrophied state in the presence of right BBB on the electrocardiogram.

TABLE I Left Atrial Abnormality on the Electrocardiogram in Patients With Right Bundle Branch Block As Related to Left Ventricular (LV) Hypertrophy Defined Pathologically

LV Size	Patients (n)	Observer 1 n	Observer 1 %	Observer 2 n	Observer 2 %
>177 g					
Hypertrophied	12	9	75	7	58
Normal	11	2	18	1	9
>200 g					
Hypertrophied	9	7	78	6	67
Normal	14	3	21	2	14

The performance of the observers can be expressed in the conventional terms of sensitivity and specificity. With LV hypertrophy defined as >177 g, observer 1 had a sensitivity of 75% and observer 2 of 58%; observer 1 had a specificity of 82% and observer 2 of 91%. With a definition of LV hypertrophy >200 g, observer 1 had a sensitivity of 78% and observer 2 of 67%; observer 1 had a specificity of 79% and observer 2 of 86%.

An evaluation of interobserver variability in recognizing the presence or absence of LA abnormality showed agreement in 21 of 23 cases (91%). The effect of this variability on results is presented in Table I.

The results of using conventional criteria for diagnosing LV hypertrophy (>177 g) in the presence of right BBB in our patients were as follows. No cases of LV hypertrophy were diagnosed with the Lewis index and there was 1 false-positive result. No cases were diagnosed with the Sokolow index. An R wave >7.5 mm in aVL was present in 1 of 12 cases, and an intrinsicoid deflection in V_5 or V_6 ≥ 0.05 second was present in 3 of 12 patients with LV hypertrophy. The latter criteria were false-positive in 1 patient. Left axis deviation >−30° was present in 13 patients. However, in only 6 patients was LV hypertrophy confirmed, leaving 7 instances of false-positive results. Tall R waves in V_5 or V_6 (arbitrarily defined as >15 mm) were seen in only 3 patients: 2 had LV hypertrophy and the other was a false-positive result.

Discussion

Our data show that recognition of LA abnormality on the electrocardiogram can be used to differentiate LV hypertrophy from the normal-size heart in the presence of right BBB. The sensitivity and specificity achieved in this study further substantiate this. LA abnormality as an electrocardiographic criterion was comparable or superior to conventional criteria commonly recommended for use in the diagnosis of LV hypertrophy in the absence of right BBB.[3]

The results of using recommended conventional electrocardiographic criteria for diagnosing LV hypertrophy in the presence of right BBB were unacceptable. These results have previously been substantiated by Booth et al,[22] who found that only 1 of 15 patients with

LV hypertrophy and none of 22 patients with combined hypertrophy could be diagnosed by the usual criteria in the presence of right BBB. However, some electrocardiographic textbooks still advocate the use of conventional criteria for the diagnosis of LV hypertrophy in the presence of right BBB.[14,19]

The definition of the magnitude of the LV mass constituting LV hypertrophy is arbitrary. Our own data suggest that a weight >177 g exceeds the normal range at a high probability.[17] However, a ventricular mass >200 g satisfies all criteria published for a hypertrophied left ventricle.[13,23] Only a modest difference in our results was noted regardless of the definition chosen. It is important to appreciate the reliability of the methods used in this study to determine specific ventricular mass in contrast to the unreliable indexes of wall thickness measurements.[24]

Our study was restricted to postmortem data of male patients. Studies of LA abnormality in living patients with right BBB and angiographic or echocardiographic determined LV mass would be of interest. Furthermore, we had no patients with mitral stenosis and congenital heart disease, so our results may not be applicable to them.

Observer variability was evaluated as part of this study and found to be acceptable, accounting for only a modest difference in results. Satisfactory observer recognition of LA abnormality was noted by Morris et al[1] and Forfang and Stoke.[25]

Automatic Computer Processing of Digital 2-Dimensional Echocardiograms

ANDREW J. BUDA, MD, EDWARD J. DELP, PhD, CHARLES R. MEYER, PhD, JANICE M. JENKINS, PhD, DAVID N. SMITH, BSE, FRED L. BOOKSTEIN, PhD, and BERTRAM PITT, MD

Quantitative studies of left ventricular function using 2-dimensional echocardiography have been limited because of a lack of computerized methods to automatically analyze the echocardiographic images. Previous computer efforts have been directed at digitizing the video output of the 2-D echocardiogram, but this digitizing method has significant limitations. A direct digitization method that produces improvement in signal-to-noise ratio and, subsequently, improved automatic detection of endocardial and epicardial borders, was developed. With definition of these edges, left ventricular global and regional analysis is possible frame by frame so that dynamic changes in cardiac function may be assessed throughout the cardiac cycle. Further technologic advances in 2-D echocardiographic acquisition and image processing should allow computer processing of 2-D echocardiographic data in real time.

Two-dimensional echocardiography (2-D echo) is particularly well suited to left ventricular (LV) functional analysis, in view of the many unique tomographic views that are available for study. However, assessment of LV function by 2-D echo remains largely qualitative because of intrinsic limitations of the ultrasound data, poor border definition in the stop frame video image, and the tedium of manual tracing of appropriate images.[1] Despite these limitations, operator-defined 2-D echo video images of tomographic LV sections have yielded important quantitative information concerning LV volume,[2,3] mass,[4] and function[4–6] with acceptable error.

Automatic computer processing of 2-D echo images would avoid the excessive time, labor, and subjectivity of manual tracing and would ultimately improve the reliability and validity of quantitative measures. Various techniques[7–10] for digitizing single frames of 2-D echo information are unsatisfactory because of the lengthy time required for digitizing a single frame of information, which eliminates any real-time capability, and the significant deterioration of the image as it is transferred through several optical systems into the computer memory.

Recently, Garcia et al[11] described an interface to a standard medical imaging computer from the video output of the 2-D echo unit or its videotape recorder. After space-time smoothing, they could automatically detect endocardial interfaces by standard threshold and second derivative methods. This report summarizes our recent work in computer acquisition and processing of 2-D echo images to quantify LV global and regional function. Our efforts initially involved acquisition and processing of 2-D echo video data,[12] but more recently we developed a method of direct-line data acquisition for 2-D echo.[13] Using the directly acquired data, we have used a number of edge detection algorithms to determine most anatomically appropriate borders. In parallel with this, we have developed a program for LV functional analysis for quantitative studies.

Methods

Digitization and processing of 2-D echo video data: Our initial attempts at computer processing of 2-D echo images were performed using a medical imaging system coupled to the video output of our 2-D echo unit.[12] The parasternal LV short axis at the midpapillary muscle level was digitized into

FIGURE 1. A parasternal, left ventricular, short-axis, video output–acquired 2-dimensional echocardiographic image after processing with superimposition of endocardial and epicardial edges.

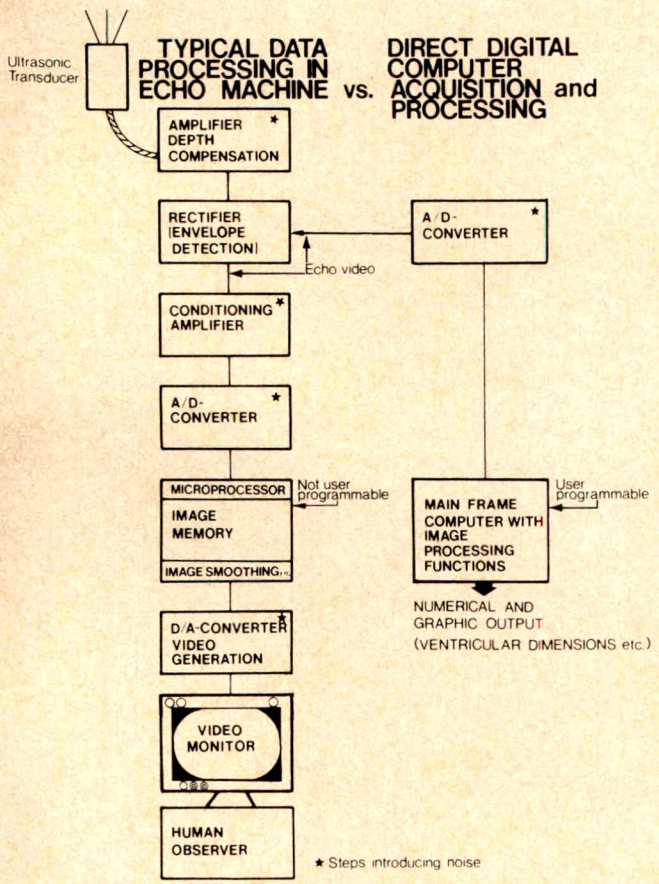

FIGURE 2. The processing steps in a commercial sector scanner and our method of direct digitization of the envelope-detected signal. Several steps of noise introduction are avoided by the direct digitization.

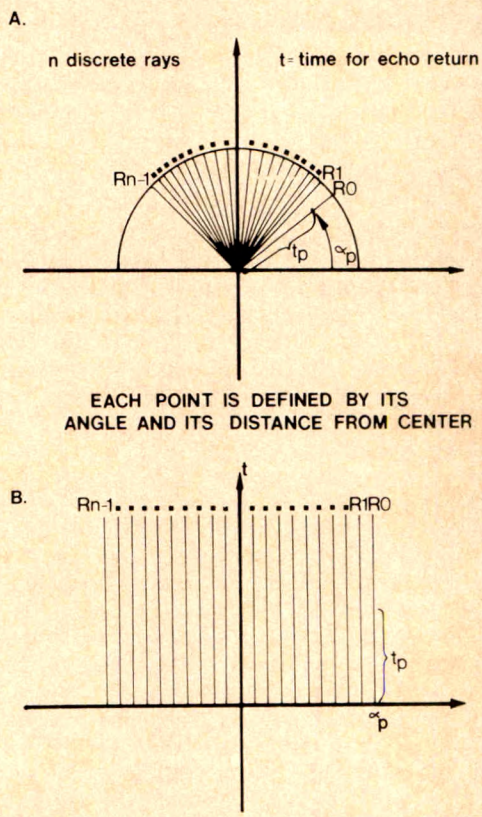

FIGURE 3. The mapping of the sector B-mode fan format (**A**) into a rectangular matrix (**B**).

a 64 × 64 array at 30 frames/sec and stored on magnetic tape for further processing. A total of 20 cardiac cycles were collected, electrocardiogram gated on the R wave. These digitized data were transferred by way of magnetic tape to the University of Michigan Computer and Image Processing Research Network.

Our processing began with the spatial averaging of time-aligned frames to produce a composite cardiac cycle of 29 images. Spatial smoothing further eliminated noise. An axially applied gradient method using 12 radial chords spaced 30° apart and originating at the center of the LV cavity was used to identify endocardial and epicardial boundaries. This approach produced short-axis LV images that were anatomically appropriate (Fig. 1).

Real-time line-mode data acquisition: Wells and Woodcock[14] distinguished between 2 approaches to echo

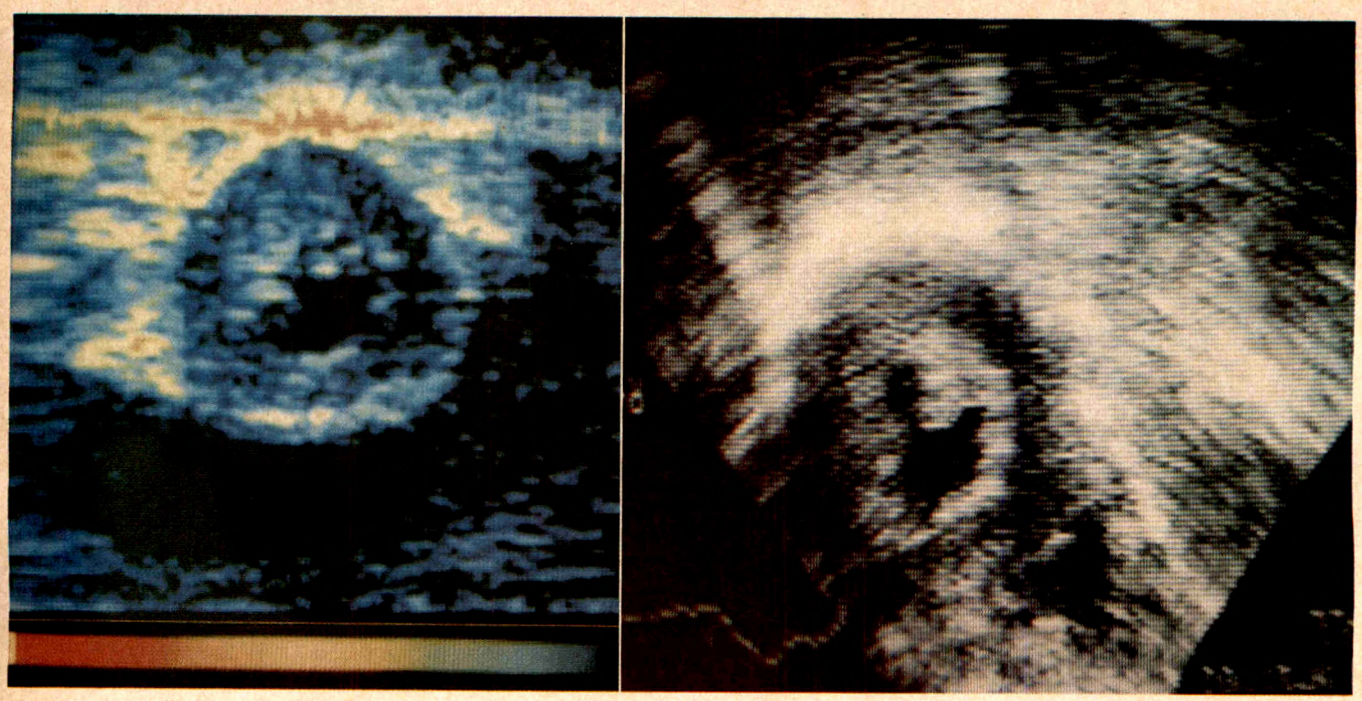

FIGURE 4. Left panel, a parasternal left ventricular end-systolic 2-dimensional echocardiographic image taken directly from the video display. **Right,** the same image acquired using direct-line mode digitization. The shape of the left ventricle is somewhat distorted because of the rectangular matrix format, but endocardial and epicardial definition is improved.

signal digitization. They termed methods which digitized the usual visual output of the echo unit "digitization of analog recordings" and termed methods in which the radio frequency (RF) signal or the envelope-detected signal was directly fed to an A/D converter "direct digitization." The term "line-mode data" has been applied to data digitized along the ultrasonic line of sight with positional information.[15]

To further improve the data at its source, we implemented direct-line digitization of our 2-D echo data (Fig. 2). We modified our computer's video A/D converter for horizontal and vertical synchronization by external digital signals. The analog section was rebuilt to adapt to the post-time-gain compensation envelope-detected RF signal from the echo machine. The pixel clock that determines the sampling rate along a line was set to 2 MHz.

From the digital-beam steering logic in the phased-array echo machine, 2 synchronization signals were derived: 1 for the firing of the center transducer element and 1 at the beginning of the first fan beam. The envelope-detected signal was amplified and transmitted directly to the A/D converter through a coaxial cable. Synchronization signals were sent through line drivers and coaxial cable to the synchronization input of the A/D converter. The process was controlled by an assembly language program with the same features as the television image digitization control programs, except that the image size was flexible to 128 × 256 pixels. R-wave triggering was used to synchronize the digitization.

The B-mode signal fan rays were thus mapped into a rectangular matrix (Fig. 3). Since 128 fan lines were produced by the echo machine and all of them were digitized, there was no data loss within a single fan frame (Fig. 4). However, the digital transfer rate of the whole frame to magnetic disk was too slow to begin acquisition of the next fan frame. Thus, only every other fan frame was digitized. The row index of a matrix element was the ray number in which a specific resolution element was sampled; the column index is the time of sampling measured from the center element transmit pulse. Only straight lines through the center of the source data coordinate system map into straight lines in the rectangular data matrix. An M-mode reconstruction from the columns of the rectangular matrix represents M-mode lines along the fan lines; an M-mode reconstruction along any other line is possible using the mapping function. Frame-to-frame and cycle-to-cycle averaging techniques for noise reduction are implemented easily in the software of this system using the programming language.

Digital processing of line-mode data: In our initial work, the images at the same location in the cardiac cycle were temporally averaged to produce a representative cardiac cycle. The images were then spatially smoothed and a 1-dimensional axial-gradient operation was performed. Regional wall measurements were digitally computed from the sequence of composite images to assess dynamic changes in wall thickness and chamber size throughout the entire cardiac cycle. Each frame was analyzed as a separate image and the adjacent frame redundancy was not exploited after the average cycle images were spatially registered.

We have extended our previous work of boundary detection and estimation of LV wall thickness and volume by treating the images as a problem in time-varying image analysis.[16] As the heart contracts, it is rotating, translating, and deforming. The problem of locating the endocardial boundary is treated as a problem of tracking a boundary of an object as it moves through a scene.[17]

The edge detector we use is a modified version of the axial gradient method previously described.[12] The algorithm begins by finding the center coordinates of the heart chamber in each frame. The images in our initial studies are interpolated to sector format from the line-mode format. The center is found by starting at any point within the chamber and locally

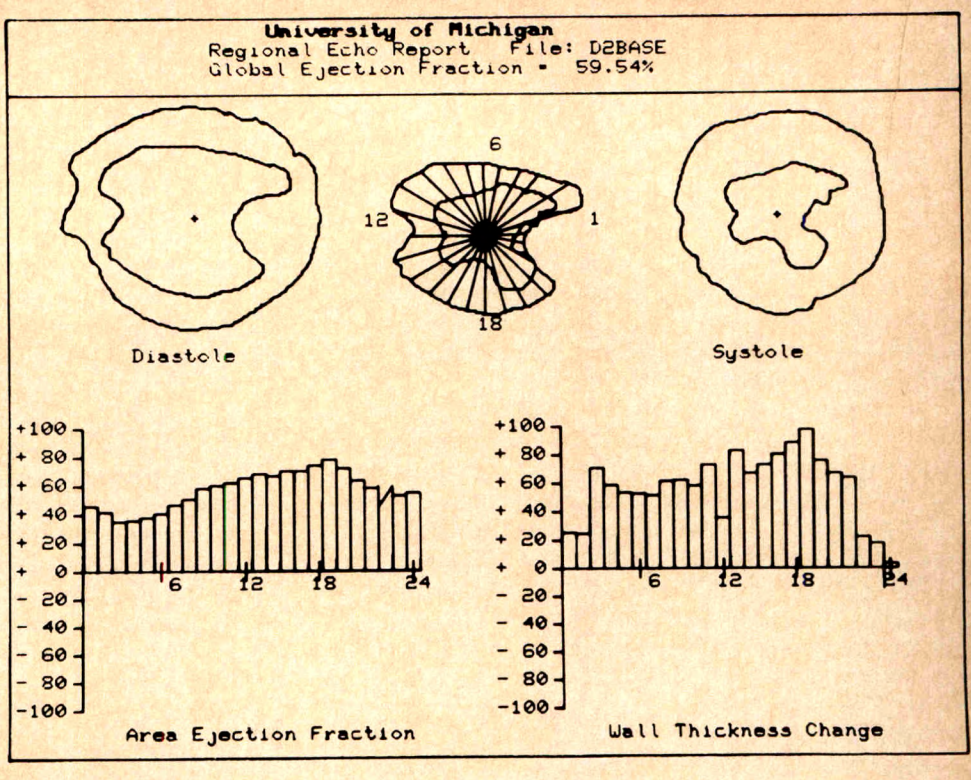

FIGURE 5. Regional analysis program used for quantitative 2-D echo studies. See text for details.

searching with a thresholding algorithm to find the endocardial boundaries. The locations are then averaged to obtain the center of the chamber. If the thresholding algorithm cannot find the endocardium in a region due to each dropout, that local region is not used to estimate the center of the chamber. This method is a fast and accurate technique for finding the center of the chamber, because the endocardial borders are as easily found by local thresholding. Once the center coordinates of each frame are found, the algorithm starts from the center point and moves along rays separated by 30°, computing the first derivative of the gray levels along the ray. The endocardium is assumed to be located where the derivative changes sign. The endocardium is found by starting at a location at the edge of the image. The derivative is computed as the ray is searched inward; when the derivative changes sign in this direction, the epicardial border is located. The edge points are then connected to form closed contours using linear interpolation. To minimize artifacts in the boundaries using this algorithm, we are investigating the use of a connectivity test to determine if the boundary has sharp changes. This is manifested by a small radius of curvature in the boundary. If the connectivity test fails in that a small radius of curvature is found in a boundary, we use this as a constraint in the algorithm to force the detector to find edges that do not have sharp boundaries. Our results using the connectivity test are only preliminary but are very promising.[18]

The edge detector described above is a static edge detector in that it operates on single frames in the cardiac cycle. We are exploiting the temporal redundancy inherent in the data. While there are various approaches to this problem, we are considering a simple method: difference pictures. Difference pictures are created by obtaining the frame difference between the current frame in the cardiac cycle and the previous frame. After thresholding, this difference picture then indicates regions in the image where the heart has moved. The edge detector algorithm described above is modified so that only regions in which the heart wall has moved are used in searching for the edges in that frame. This aids in finding the edges because the difference pictures indicate where along the rays the edges in the current frame are located. This technique can also be used to limit how much the edges are allowed to change from frame to frame.

Using this approach, we found that cycle averaging and spatial smoothing may not be necessary with the directly digitized line-mode data. In fact, the edges found for each image in a cycle have fewer artifacts and tend to preserve edge connectivity throughout the cycle.

Quantitative analysis of the left ventricular image: In parallel with our efforts at 2-D echo direct line-mode digital acquisition, image processing, and edge detection, we have developed a program to analyze regional LV function. This analysis may be applied to any LV short-axis projection and the derived data in combination with long-axis data may be used to estimate global LV function and mass using well-described algorithms such as Simpson's rule.

In this analysis, the endocardial and epicardial borders of the LV at end-diastole and end-systole are manually entered into the computer using a Tektronix digitizing tablet. A menu displayed on the image device guides and prompts the operator for data input. The data input consists of epicardial and endocardial borders, external alignment points for the systolic and diastolic images, and 5 cm magnification calibration points. Once all the data have been entered, the program calculates the center of mass of the diastolic endocardial border, the rotation angle, and translation coordinates for alignment of the systolic borders over the diastolic borders. These aligned borders are then stored in a protected disk file for archival and research use. Calculations are performed using the center of mass of the end-diastolic endocardial border as the reference point. The continuous borders are separated into 24 segments, each of 15°, for calculation of regional ejection fraction, regional wall area, and regional wall

thickness (Fig. 5). There is a graphic display of proportional change, diastole to systole, along with the segmented systolic and diastolic borders.

Discussion

The interpretation of LV function by 2-D echo largely remains a descriptive technique requiring expert observers. Quantitative analysis has involved manual delineation of endocardial and epicardial boundaries of end-diastolic and end-systolic frames by trained operators. Other frames of the cardiac cycle are generally not analyzed because of the time and labor involved. The ability to further automatically process these 2-D echo images should improve our ability to quantitate 2-D echo data, provide a more objective approach to interpretation, and improve interobserver variability. The major limiting factor to the development of computer processing of 2-D echo has been the long acquisition times required to digitize a single frame of data. However, digital interfaces specific to ultrasound make it possible to acquire digital 2-D echo data in real time. Owing to the inherent complex interaction of ultrasound in tissues and the several steps of processing that occur within the commercial 2-D echo unit, these digitized data are noisy.

In our initial approach to acquisition of 2-D echo data, the video output of the unit[12] was digitized. This method has several flaws. First, the resampling process required to form a video image from the line-mode data tends to produce undersampling of data in the near field and oversampling in the far field. Second, the ultrasound frame generation may not match the video frame rate. Third, the scan converter within the echo unit maps the information into a range of gray values with a dynamic range matched to the human visual system; however, the usable dynamic range of the data is significantly greater. Fourth, the averaging technique for speckle reduction is usually not under user control. Fifth, the video image data depends on the processing performed by the echo technician, who varies the control settings on the echo unit to achieve an image that looks best to the human observer; however, this image may not necessarily be optimal for computer processing. For these reasons, we approach the digital acquisition of 2-D echo data through direct line-mode digitization.[13] With this approach, RF envelope-detected data are digitized before data transfer to the digital scan converter. This avoids the introduction of noise at several levels of data conversion and provides improved signal-to-noise ratios.

Robinson and Williams[15] indicated that this method is superior to other methods of digitization for 2-D echo processing. In addition, this line-mode digitization method has several advantages over conventional video image digitization. First, the ultrasound frame generation rate is equal to the A/D frame conversion rate; this condition is not necessarily fulfilled by video image digitization. Second, the envelope-detected signal is independent of all control settings on the echo unit except for gain control. Third, the dynamic range of the 8-bit line-mode data significantly exceeds that of the typical 4- to 6-bit output of the digital scan converter used for video data acquisition. For these reasons, we believe that line-mode data digitization is presently the preferred method of ultrasound data acquisition for computer processing.

Image processing and algorithm development have been undertaken on our computer system. After applying Laplacian, Sobel, trapezoidal, and high-pass filtering edge detection routines, our approach of axial gradient edge detection appears to be the simplest and most accurate for providing anatomically appropriate endocardial and epicardial definition. With the line-mode digitization, temporal or spatial smoothing or both may produce artifacts in our automatically derived edges.[16] These smoothing techniques may be better suited to 2-D echo video data, for which they provide some improvement in signal-to-noise ratios. Further algorithm development, testing, and validation are required before clinical application of these techniques is attempted. Although our axial gradient technique is used, we believe that edge detection would be improved by using a time-varying image analysis approach[17,18] in which edge redundancy in frame-by-frame analysis would be used to provide further improvement in edge tracking. This form of dynamic scene analysis has been used in other imaging problems with success.[19,20]

Assuming that appropriate edges can be found and validated, a quantitative approach to global and regional analysis would then be necessary. Several attempts at LV function quantitation have been undertaken with manually defined edges, with variable success.[2–6] Although good correlations with standard measurements have been achieved, there remains 10 to 20% variability in the measurement of LV volumes and mass. This variability derives from tomographic trajectory, poor endocardial definition, observer error, and, of course, additional variability of the gold standard method.[21] For instance, in contrast LV angiography, the contrast material produces volume loading and a negative inotropic effect,[22] contributing to discrepancies with other imaging techniques. Automatic methods of edge detection and quantitation for 2-D echo should reduce interobserver variability but will not influence these other factors, which require different solutions. A major impact of automatic quantitated processing will be the time saved in analysis and the ability to measure dynamic information contained within the entire cardiac cycle.

The quantitative analysis of regional function that we have developed is similar to approaches previously described.[6,11] However, controversy continues regarding the use of coordinate systems and correction of 3-D movement.[23] This problem is best illustrated by the variability of regional analysis, which depends on whether a fixed or floating center of mass is used.[6] Although axial coordinates have been traditionally used with most cardiac imaging modalities, the unique tomographic information provided by 2-D echocardiography permits an approach to shape descriptors using Fourier shape analysis or mean tensor analysis.[24] These forms of analysis may circumvent the problem introduced with a coordinate, axial approach to quantitative regional LV function.

We anticipate further improvements in digital data acquisition, image processing, development of edge

detection algorithms, and methods of quantitation of 2-D echo images. These improvements should then provide a basis for meaningful 3-D reconstruction[25] of 2-D echo images.

Early Degradation of Collagen After Acute Myocardial Infarction in the Rat

RICHARD O. CANNON, III, MD, JAGDISH W. BUTANY, MD, BRUCE M. McMANUS, MD, PhD, EDITH SPEIR, BS, ALAN B. KRAVITZ, BS, ROBERTO BOLLI, MD, and VICTOR J. FERRANS, MD, PhD

After acute myocardial infarction (MI), proteolysis of necrotic myocardium is mediated by infiltrating inflammatory cells at the infarct margins. Collagen forms a structural fibroskeleton in healthy myocardium, and after MI this collagen may continue to provide significant tensile strength to the necrotic muscle wall. To determine whether collagen is also degraded (which might decrease infarct wall strength) and, if so, whether inflammatory cell proteases are implicated, hydroxyproline was measured from infarct zone and normal zone tissue from 24-hour infarcts produced in control rats and in rats made leukopenic (white blood cell count $<300/mm^3$) by prior whole-body irradiation. Hydroxyproline was measured after precipitation of tissue homogenates with trichloroacetic acid to separate partially degraded collagen from larger collagen molecules that might retain structural importance. At 24 hours, there was significant (25%) collagen degradation in the infarct zone ($p < 0.01$) in control rats but not in leukopenic rats. Tissue cell counts revealed a paucity of inflammatory cells in the infarct margins in leukopenic rats. Electron microscopic studies revealed greater preservation of collagen in the 24-hour-old infarcts of irradiated leukopenic rats compared with those of control rats. These results suggest that at 24 hours after experimental MI in the rat, there is significant collagen degradation mediated by inflammatory cell proteases.

Collagen forms a structural network for the attachment and alignment of heart muscle cells.[1] The arrangement of this network probably prevents slippage of myocytes during systole, tends to maintain the patency of capillary lumina during systole, and provides tensile strength to the heart muscle wall. After myocardial infarction (MI), when heart muscle cell death and degeneration occur, this collagen fibroskeleton may be important in maintaining the integrity of the ventricular wall until new collagen deposition and scar formation begin. We have demonstrated that proteolysis of necrotic myocardium significantly increases by 18 to 24 hours after experimental MI in the rat,[2] concomitant with an influx of inflammatory cells at the infarct margins. It is possible that inflammatory cell proteases jeopardize existing collagen soon after MI, potentially leading to wall thinning or rupture before new collagen formation. This study assesses the effect of inflammatory cell proteases on left ventricular myocardial collagen after experimental MI.

Methods

Experimental myocardial infarction: Sprague-Dawley male rats that weighed 250 g and had been maintained on rat chow (Purina) and water ad libitum were anesthetized with ether. A left thoracotomy was performed, and the heart was manually expressed from the chest cavity. A 4-0 silk suture ligature was placed around the left coronary artery at the level of the tip of the left atrial appendage.[3] The heart was rapidly repositioned in the chest, the wound closed with a previously placed purse-string suture, and the rat resuscitated. This model results in transmural infarcts of 30 to 50% of the left ventricle, with sparing of the interventricular septum. An operative mortality of approximately 25% was encountered and deaths after 6 hours postinfarction were uncommon. The rats were killed at 24 or 72 hours for collagen content determination and histologic studies. Unoperated control rats were also killed for comparison. Another group of rats underwent whole-body irradiation with 800 rad from a cesium-137 source (Gammacell 40, Atomic Energy of Canada). Two days after irradiation, significant leukopenia as determined by hemocytometer counting[4] developed in all rats (Table I). At this time, the rats underwent coronary artery ligation as described above. There was no excess mortality in this group compared with that of the nonirradiated controls. By 24 hours after in-

TABLE I White Blood Cell Count—Control and Irradiated Rats

	Unoperated	24 Hours After Myocardial Infarction
Controls	13,275 ± 811 n = 13	14,167 ± 651 n = 9
Irradiated	3,016 ± 258* n = 29	302 ± 56* n = 24

White blood cell counts expressed as cells/ml, mean ± standard error. Counts on unoperated, irradiated rats were measured at 48 hours after 800 rads of whole-body irradiation (before coronary artery ligation) and at 24 hours after ligation (72 hours after irradiation).
* $p < 0.001$ versus respective control.

farction (3 days after irradiation), profound leukopenia was found in all rats (Table I). The rats in this group were then killed for myocardial collagen content determination and histologic study. Because of an increasing mortality rate >3 days after irradiation, collagen measurements and histologic studies were not performed 72 hours after infarction in leukopenic rats.

Collagen measurements: Collagen content was assessed by measuring hydroxyproline, which comprises a relatively constant 14% of collagen molecules and is found in few other tissue proteins in significant quantity.[5] After the rats were killed by a blow to the head, the heart was rapidly removed and rinsed in normal saline solution. The infarct was excised from the remaining myocardium and transmural samples of the infarct zone, as well as normal tissue from the interventricular septum (normal zone), were separately dried in an oven at 60°C for 1 hour. The tissue, ranging in dry weight from 25 to 40 mg, was homogenized in 2.0 ml of water. The homogenate from each sample was precipitated in 0.5 ml cold 50% trichloracetic acid (TCA, final concentration 10%) in order to separate large protein molecules from partially or completely degraded peptides (less than approximately 12,000 molecular weight), which would remain in the supernatant.[6] After centrifugation at 5,000 rpm for 20 minutes at 5°C, the supernatant was removed and the precipitate resuspended in 2.0 ml of water. Then, 0.25 ml of 1 *M* sodium hydroxide and 2.0 ml concentrated hydrochloric acid (final concentration approximately 6 *M*) were added to each sample. After thorough mixing with a vortex mixer, the samples were placed in Teflon-capped tubes and heated in an oven at 110°C for 12 hours. Hydroxyproline assay by the colorimetric method of Prockop and Udenfriend[5] was performed after completing the acid hydrolysis. To ensure that TCA did not alter hydroxyproline during acid hydrolysis, duplicate samples of 0.5 m*M* hydroxyproline (H6002, Sigma) and three 1:1 serial dilutions (0.25 m*M*, 0.125 m*M*, 0.063 m*M*) were assayed in an identical manner as the rat myocardial tissue. The assay results were plotted against the known standard concentrations, with excellent correlation ($r = 0.95$).

Microscopic examination: Another group of control and irradiated rats underwent coronary artery ligation and were killed at 24 hours. The hearts were rapidly excised and placed in normal saline solution until contraction ceased, then fixed in 10% acetate-buffered formalin solution or 3% glutaraldehyde. Formalin-fixed hearts were sliced from base to apex in a plane parallel to the atrioventricular groove beginning at the level of the suture ligation, resulting in 4 transverse slices each 2 to 2.5 mm thick. After embedding in paraffin, 6-μm-thick histologic sections were obtained from the middle of each slice and stained with hematoxylin-eosin. The histologic sections of all 4 slices from each heart were projected onto a screen at a 10-fold magnification, and the areas of normal and infarcted myocardium measured by planimetry. Infarct size was determined by averaging the percent infarcted area in each of the 4 slices. Kodachrome slides were taken at 400 × magnification of 10 representative areas of infarct margins from 5 control and 5 irradiated rats at 24 hours after infarction. The slides were projected on a grid-arrayed screen of known dimensions. Polymorphonuclear leukocytes (PMNs) were counted by 2 observers without knowledge of the identity of the slides. The average cell count of 10 slides for each rat was expressed as the number of PMNs/mm^2 of tissue section.

For electron microscopic study, the hearts were cut transversely into 5 slices, which were placed in 3% glutaraldehyde in 0.1 *M* phosphate buffer, pH 7.2. From the third of these slices, small tissue samples were obtained from the infarct margins, the infarct core, and normal septal myocardium. These samples were washed with several changes of 5% sucrose in 0.1 *M* phosphate buffer, pH 7.2; postfixed with 1% OsO_4 in Millonig's phosphate buffer, pH 7.2; dehydrated with a graded series of ethanols and propylene oxide; and embedded in Maraglas using flat embedding molds to preserve the orientation of the endocardium. One-thick sections of Maraglass-embedded tissues were stained with alkaline toluidine blue and examined with a light microscope in order to select areas for ultrathin sectioning. Ultrathin sections were stained with ethanolic uranyl acetate and lead citrate and examined with a JEOL 100B electron microscope at an accelerating voltage of 80 kV.

Statistical analysis: All data were analyzed using unpaired two-tailed Student's *t* test. A p value <0.05 was considered significant. Data are expressed as mean ± standard error of the mean.

Results

Measurement of TCA-precipitable hydroxyproline in unoperated rats revealed no significant difference between the collagen content of left ventricular free wall (9.2 ± 0.5 nmol/mg dry weight) and septum (10.6 ± 0.8

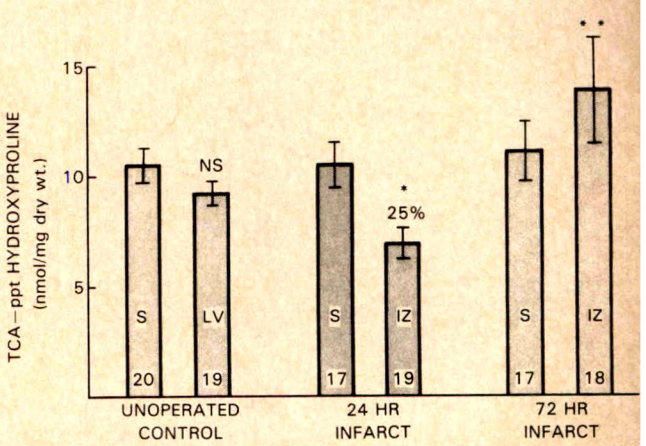

FIGURE 1. Hydroxyproline content from unoperated rats and control rats at 24 and 72 hours after coronary artery ligation. There was no significant difference between septum (S) and left ventricular free wall (LV) in unoperated rats. Note the significant decline in hydroxyproline content in infarct zone (IZ) tissue 24 hours after infarction compared with unoperated control left ventricular tissue. By 72 hours, there is a significant increase in hydroxyproline content of the infarct zone compared with 24 hours postinfarction IZ tissue. Results are expressed as mean ± standard error. Number at the bottom of each bar indicates the number of rats studied. * $p < 0.01$ versus unoperated control LV tissue. ** $p < 0.001$ versus 24-hour IZ. TCA = trichloroacetic acid.

nmol/mg dry weight; Fig. 1), in agreement with previously published measurements in rat myocardium.[7] There was no significant difference between the collagen content of normal zone tissue from the ventricular septum (10.6 ± 1.1 nmol/mg dry weight) of rats of 24 hours after coronary artery ligation when compared with septal tissue from unoperated control animals. However, there was 25% reduction of TCA-precipitable collagen in the infarct zone (6.9 ± 0.7 nmol/mg dry weight, $p < 0.01$) at 24 hours after infarction compared with left ventricular tissue of unoperated rats. Conversely, rats made leukopenic by whole body irradiation before infarction had insignificant collagen degradation (9.9 ± 1.2 nmol/dry weight, Fig. 2) at 24 hours after MI (3 days after irradiation) in infarct zone tissue compared with left ventricular tissue of unoperated control animals 3 days after irradiation (11.0 ± 0.8 nmol/mg dry weight).

Nonirradiated rats had a greater amount of collagen in the ischemic zone at 72 hours (13.9 ± 2.5 nmol/mg dry weight than at 24 hours (6.9 ± 0.7 nmol/mg dry weight, $p < 0.001$) after infarction (Fig. 1). Collagen content in septal tissue was not significantly different at 24 hours (10.6 ± 1.1 nmol/mg dry weight) and 72 hours after MI (11.2 ± 1.3 nmol/mg dry weight).

Histologic observations: As determined by planimetry, the sizes of 24-hour-old infarcts were identical in control (43.5 ± 2.8% of left ventricle, n = 17) and irradiated animals (43.5 ± 3.4% of left ventricle, n = 13) at 24 hours after MI. Light microscopic comparison of transverse ventricular sections of normal and irradiated rats 24 hours after acute MI revealed a marked diminution of the acute inflammatory response in the irradiated animals (Fig. 3). The distribution of inflammatory cells at the margin of infarcted and viable myocardium was similar in both animal groups. Correspondingly, myocyte damage and nuclear debris were most evident at the infarct margins, although they were much more extensive in the control rats.

Tissue cell counts: Cell counts from the border zone of control rats at 24 hours after infarction demonstrated an average of 416 ± 43 PMNs/mm^2 of tissue section, with prevalent "nuclear dust" representing leukocytes in various stages of degranulation and degeneration. Conversely, irradiated rats demonstrated a paucity of PMNs: 75 ± 11 PMNs/mm^2 ($p < 0.001$ versus control animals).

Electron microscopic observations: Electron microscopic examination of infarct core tissue from the control and irradiated rats revealed the known ultrastructural changes of ischemic necrosis in the myocytes.[8] An infiltrate of polymorphonuclear leukocytes was present in the border zones of infarcts from control hearts (Fig. 4). In this group of hearts, the connective tissue in the border zone showed fragmentation of collagen fibrils, the damaged ends of which seemed to be disrupted into fine granules. These changes were considered indicative of degradation of collagen fibrils because of their striking similarity to those that occur in damaged collagen in other conditions (for review see Ferrans et al[9]). They were less pronounced in the infarct core and were not present in the normal zone (septum).

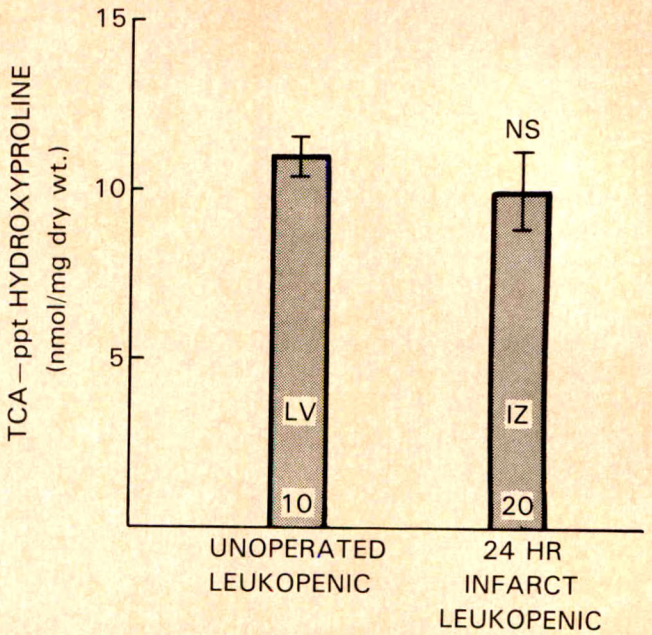

FIGURE 2. Hydroxyproline content from unoperated rats and rats at 24 hours after infarction. Both groups were 72 hours postirradiation (800 rad whole body). The hydroxyproline decrease in the infarct zones of control rats (Fig. 1) is not seen in irradiated leukopenic rats. Results are expressed as mean ± standard error. IZ = ischemic zone; LV = left ventricle; NS = not significant compared with unoperated leukopenic left ventricle; TCA = trichloracetic acid; numbers at the bottom of each bar indicate number of rats studied.

The alterations just described involved the small bundles of collagen fibrils coursing between individual myocytes as well as larger collagenous septa enveloping groups of myocytes. Tissue from the 24-hour irradiated leukopenic rats (Fig. 5) showed considerably fewer polymorphonuclear leukocytes and significantly greater preservation of collagen in the border zone and the infarct core.

Discussion

Although the association of extracellular connective tissue with myocytes has been appreciated for many years, the structural arrangement of the elaborate fibroskeleton of the heart has been demonstrated only recently. Using transmission and scanning electron microscopy, Caulfield and Borg[1] demonstrated that the network of collagen fibers in both animal and human hearts has 3 basic components. First, bundles of collagen fibers (measuring 120 to 150 nm in rodent hearts, somewhat larger in human hearts) extend between adjacent myocytes, inserting near the Z bands and the points of origin of the transverse tubular system. These intermyocyte connections appear curved in hearts arrested in systole and straightened in hearts arrested in diastole. It has been suggested that such connections align and mechanically couple myocytes, preventing slippage during systole. Additionally, these collagenous connections become thickened (250 to 300 nm in humans) in hypertrophied hearts. The second component of the collagen fibroskeleton consists of connections between myocytes and capillaries. Such connections

allow for capillary patency during high intraventricular systolic pressures and possibly explain the observation of systolic intramyocardial blood flow.[10] Most important from the standpoint of myocardial stiffness[11] may be the third component, a web network of collagen fibers that envelop groups of myocytes and have loose collagen connections between these groups, allowing slippage to occur. This weave configuration of collagen may have viscoelastic properties that contribute to left ventricular compliance.[12] Other connective tissue components, such as basal laminae, elastin, microfibrils, fibronectin, and proteoglycans also are undoubtedly important in the linkage of collagen to myocytes and capillaries.

Our experiments demonstrate significant degradation of collagen in rat MI by 24 hours after coronary artery ligation. The design of these experiments may have allowed for an underestimation of the degree of collagen degradation. Because TCA precipitates large proteins of greater than approximately 12,000 molecular weight, large, partially hydrolyzed collagen fragments that would have little or no structural importance could have been measured along with intact collagen molecules. Certainly, smaller collagen polypeptides and component amino acids with no structural significance could be separated by this precipitation technique. This collagen proteolysis was associated histologically with an influx of inflammatory cells, especially polymorphonuclear leukocytes, at the infarct margins. The fact that leukopenic rats demonstrated less degradation of collagen, as shown by biochemical measurements and ultrastructural observations, suggests that inflammatory cell proteases are responsible for collagen proteolysis. Polymorphonuclear leukocytes and marcrophages are known to contain several potent proteolytic enzymes, including collagenase.[13] Histologically, the margins of 24-hour infarcts contain polymorphonuclear leukocytes in various stages of degeneration and degranulation, changes indicative of the release of proteolytic enzymes. Collagenase is crucial for the initial degradation of collagen, although after initial cleavage by collagenase, other proteolytic enzymes contained within PMNs can further degrade collagen.[14]

During the early hours after MI, when lysis of necrotic myocytes is occurring, the collagen fibroskeleton described above would not be immediately affected by ischemia and may provide significant tensile strength

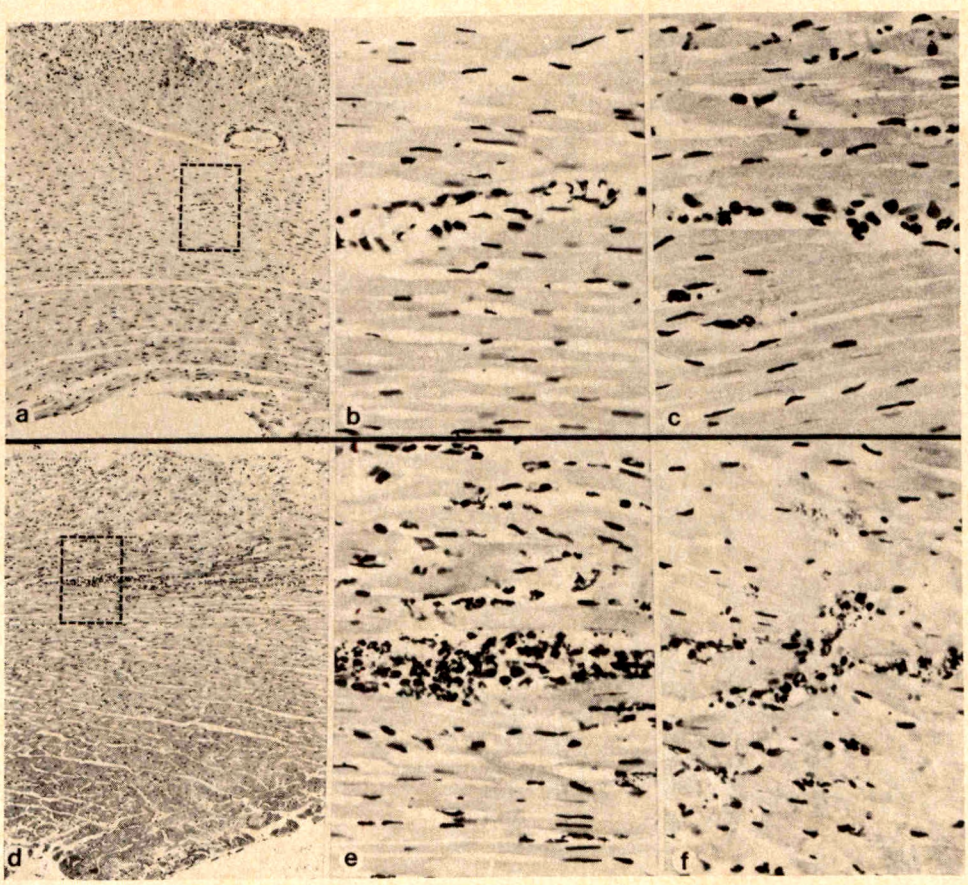

FIGURE 3. Photomicrographs of the anterior left ventricular free wall at the site of acute myocardial infarct 1 day after coronary artery ligation in irradiated (**a, b, c**) and control (**d, e, f**) rats. **a,** rare inflammatory cells are seen in the central area of the infarct in irradiated animals. **b,** higher power of the demarcated area in **a,** showing the paucity of perivascular or interstitial inflammatory cells. **c,** margins of the infarct have a few more inflammatory cells, including polymorphonuclear leukocytes and monocytes. **d,** a more pronounced inflammatory cell infiltrate is evident in the control rats. **e,** higher power of the demarcated area in **d** showing numerous inflammatory cells and early myocyte degeneration and necrosis. **f,** margins of the infarct also have numerous inflammatory cells, mostly fragmented leukocytes. Myocyte necrosis is more extensive and advanced. Hematoxylin-eosin stains; magnifications × 100 (a, d), × 550 (b, c, e, f,), reduced 48%.

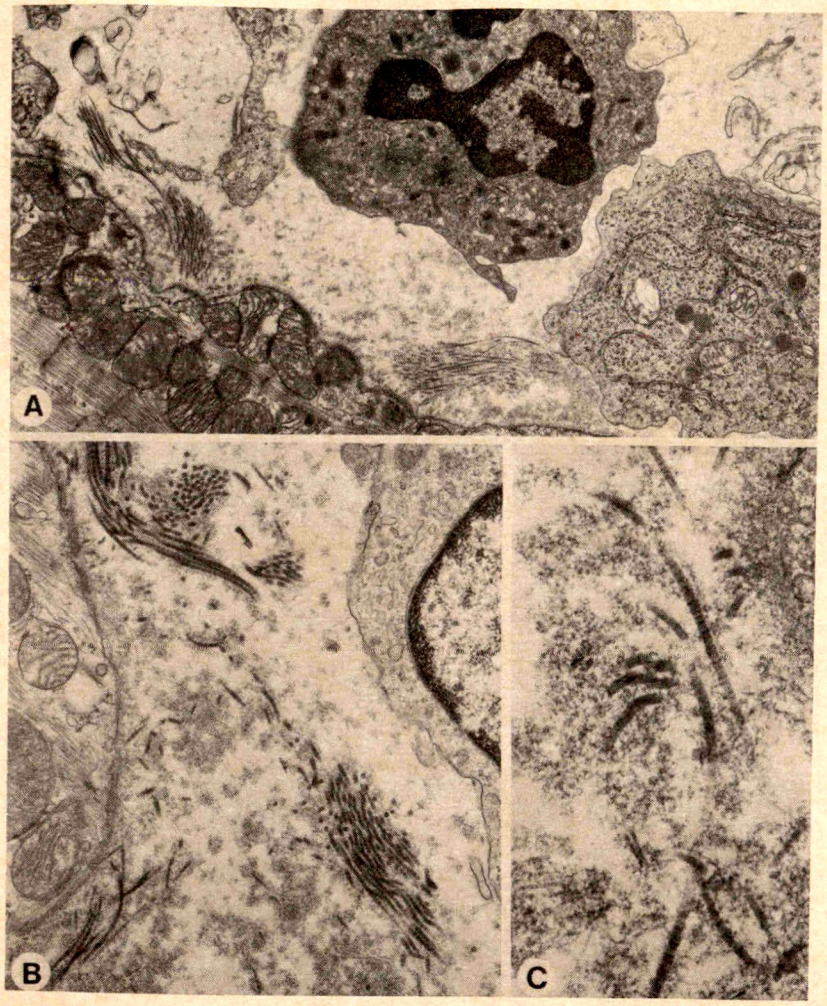

FIGURE 4. Electron micrographs of 24-hour-old myocardial infarcts from control (non-irradiated) rats. Compare with Figure 3 d–f. **A,** a polymorphonuclear neutrophil (**upper center**) and a macrophage (**lower right**) are present in border zone area with interstitial edema. Disruption of collagen bundles has occurred, even though the cardiac muscle cell is not necrotic. Magnification × 13,850, reduced 36%. **B,** higher-magnification view of area similar to that shown in A. The collagen fibrils are surrounded by connective tissue microfibrils and finely granular material of low electron density. Magnification × 19,400, reduced 36%. **C,** high-magnification view of disrupted collagen fibrils, which appear coarsely granular and terminate into masses of granular or amorphous material. Magnification × 46,500, reduced 36%.

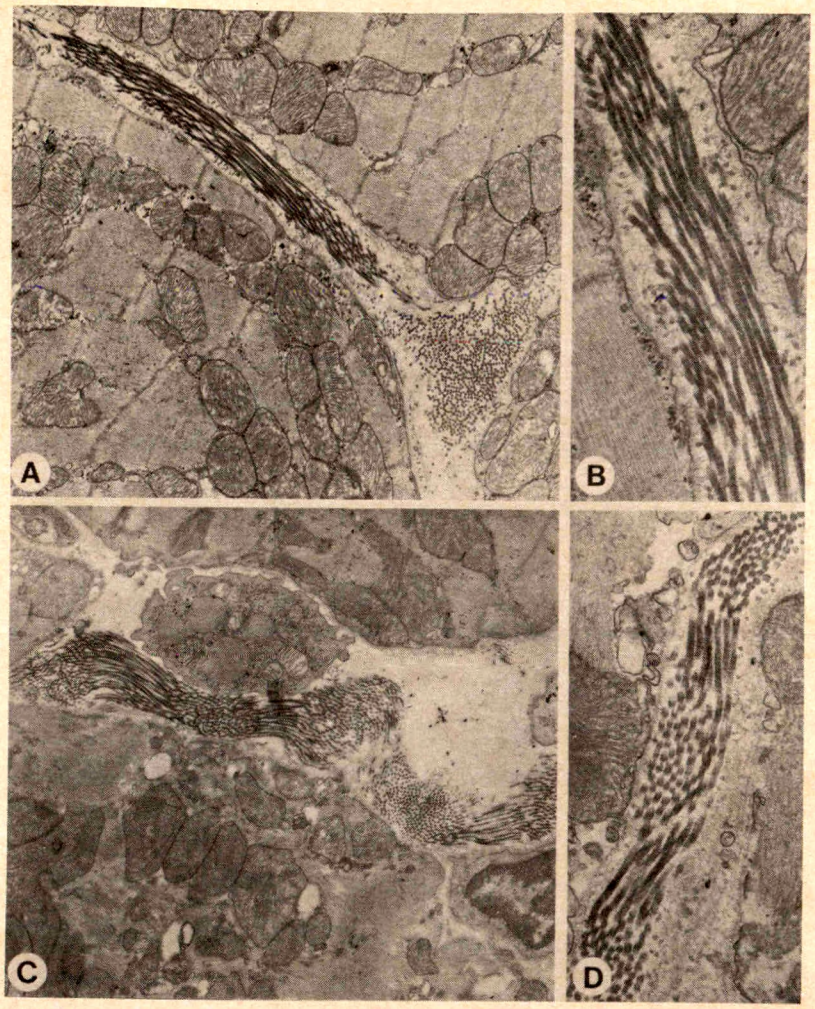

FIGURE 5. Electron micrographs of 24-hour-old myocardial infarcts from irradiated rats. Compare with Figure 3 a–c. **A,** two bundles of collagen fibrils separating nonnecrotic muscle fibers in border zone appear normal. Magnification × 14,650, reduced 36%. **B,** higher-magnification of view of part of normal collagen bundle shown at upper left in A. Magnification × 29,850, reduced 36%. **C,** normal collagen bundle is adjacent to disrupted severely necrotic myocyte (**lower left**). Magnification × 13,150, reduced 36%. **D,** normal collagen bundle separates 2 necrotic myocytes with fragmented plasma membranes. Magnification × 24,900, reduced 36%.

to the transmural infarct. In serial studies of rat myocardial infarcts, Fishbein et al[15] showed that significant fibroblast infiltration and collagen deposition are not seen until the third day after infarction. This suggests that there is a period during which the tensile strength of the infarct margin may be greatly reduced, rendering it vulnerable to thinning or rupture. Although cardiac rupture was not noted in any rats in this study, the analogy to human MI cannot be dismissed. Human infarcts demonstrate an even more intense polymorphonuclear leukocyte response than do those in rats. Serial studies of human infarcts have demonstrated that fibroblastic infiltration does not begin until 4 days after infarction, with collagen deposition occurring during the second week.[16,17] Thus, human transmural infarcts may be exposed to an even more prolonged vulnerable period between proteolysis of preexisting collagen and deposition of new collagen in the region of the infarct.

The demonstration of inflammatory cell proteases mediating infarct wall collagen degradation may have important therapeutic implications for the prevention of cardiac rupture, which still has a 10 to 20% incidence among fatal acute myocardial infarctions.[18,19] The administration of anti-inflammatory agents early after infarction, when inflammation is initiated at the infarct margin, might protect the collagen fibroskeleton from proteolysis.[20] A recent report, however, has indicated that ibuprofen actually leads to an increased incidence of scar thinning after MI in dogs.[21] Interference in the normal leukocyte degradation of necrotic tissue might be harmful, despite protection of collagen. Further experiments are being performed to clarify this issue.

Assessment of Quantitative Methods for 2-Dimensional Echocardiography

HORACE L. WYATT, PhD, ROBERTO V. HAENDCHEN, MD, SAMUEL MEERBAUM, PhD, and ELIOT CORDAY, MD

Several 2-dimensional echocardiographic (2-DE) methods were tested in vitro for accuracy of linear and cross-sectional measurements and in vivo for left ventricular (LV) volume reconstruction. With 2-DE instrument settings at low and high gains and with precise in vitro calibrations, we studied myocardial slice thickness (3.0 to 10.0 mm). The 2-DE myocardial thickness was measured by leading-trailing, trailing-leading, and leading-leading methods. Regression analysis of 2-DE versus direct measurements yielded excellent correlations for all 3 methods ($r > 0.985$), with interobserver variability $< 3\%$. Accuracy of measurement was satisfactory only for the leading-leading method (3 and 6% error at low and high gains, respectively); other methods substantially over- or underestimated thickness. Thin myocardial slices (<1 mm thick) were applied to cylinders and fixed in formalin to produce precise cavity areas (1.8 to 7.0 cm^2). Regression analysis of 2-DE versus actual cavity area gave high correlations ($r > 0.970$), and low interobserver variability ($< 4\%$) for the inner edge and leading edge methods, but the leading edge method was the most accurate (1.3 to 2.5% error). In vivo LV volumes in 7 anesthetized dogs were compared with 2-DE and cineangiography. Good correlations ($r = 0.92$) were obtained, but the inner edge method underestimated angiographic volume, whereas the leading edge method reduced the magnitude of underestimation. Thus, the leading edge method for 2-DE is most accurate not only for linear and cross-sectional measurements of the myocardium, but also for application to in vivo LV volumes.

Previous studies with 2-dimensional echocardiography (2-DE) have shown that reasonable estimates for left ventricular (LV) volume and mass can be obtained in both dogs[1–7] and man.[8–10] Nevertheless, direct quantitative assessment has been impeded because echocardiography generally underestimates volumes compared with cineangiography.[6,8,10] In a recent study,[11] 2-DE underestimated short-axis cavity area of the formalin-fixed heart. The reasons for these discrepancies are not certain, but they could result partially from an inappropriate method of measurement from the echocardiographic images. Basic measurements of LV dimensions and cross-sectional areas are required to adequately validate the most accurate method for echocardiographic measurement. Thus, the objectives of this study were (1) to determine in vitro the most accurate echocardiographic method for performing linear and cross-sectional measurements, and (2) to apply and test this method for determining LV volume in the beating heart.

Methods

In vitro studies: Three mongrel dogs were killed with an overdose of pentobarbital sodium. The hearts were removed and frozen. Using a Burkholt meat slicer, the frozen canine myocardium was sliced into sections 3 to 10 mm thick. With a calibrated needle, the thickness of each section was measured directly to the nearest 0.2 mm in a minimum of 4 locations per section. Only sections with exactly corresponding measurements in each location were used for echocardiographic study. The frozen myocardium was further sliced into long tissue sections <1 mm thick; these were wrapped around and secured with thread to 4 plastic syringe cylinders fixed in formalin and then removed from the syringe for subsequent 2-DE study. The cut end of each syringe and 1 end of each myocardial cylinder was photographed. Actual intraluminal cross-sectional area of the cylindrical standards was measured

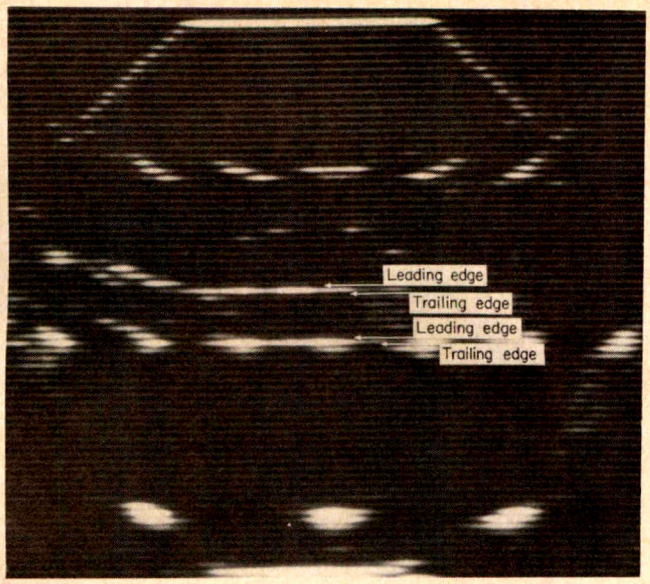

FIGURE 1. Two-dimensional echocardiographic low-gain image of a slice of myocardium interposed in the calibration box. Leading and trailing edges are designated for both upper and lower echo interfaces of the myocardial tissue. Echo images of the calibration strings are also prominent.

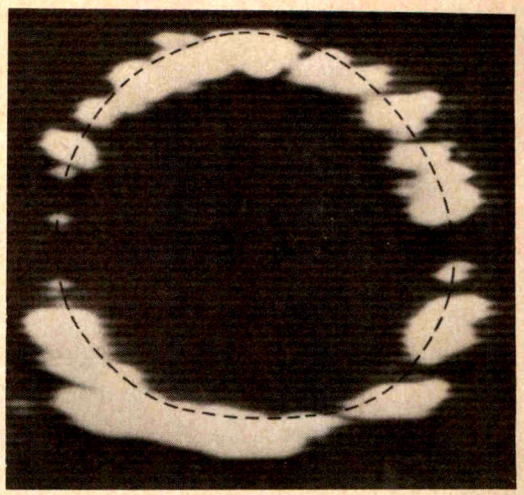

FIGURE 2. Two-dimensional echocardiographic image of a formalin-fixed cylinder of thin myocardium. **Broken line** within this image demonstrates the leading edge method. At the central top and bottom of the circle, the broken line lies at the leading edge of the image, but as the image blooms out laterally, this line is directed toward the center of the echo image. In contrast, the inner echo method would outline the inner border of the circular echo image for the entire circumference.

to the nearest 0.1 cm^2 by planimetry of photographic outlines; duplicate area measurements from both syringe (outer surface) and myocardial outlines corresponded exactly for the 4 sizes, 1.8 to 7.0 cm^2.

The myocardial frozen sections and the formalin-fixed cylinders were placed separately into a waterbath along with a calibration phantom box and imaged with a 90° mechanical sector scanner unit (ATL Mark III) over a wide range of electronic gain settings. Figure 1 shows a low-gain 2-DE image of a section of myocardium 6 mm thick. Both the upper and lower surfaces of the tissue exhibit echocardiographic interfaces, separated by the absence of echo between them. For each interface, leading and trailing edges are designated. Low gain was defined as the lowest possible setting at which tissue targets were well visualized, and high gain as a standardized number of incremental electronic gain settings. Low- and high-gain settings were produced by changing only the damping adjustment while other instrument parameters were kept constant. With stop-frame analysis of 2-DE images, myocardial thickness was measured directly from the screen by 3 commonly used methods: (1) The leading-trailing method measures thickness from the leading edge of the upper echo to the lower echo interface, and therefore includes the width of both echo interfaces. (2) The trailing-leading method measures thickness from the trailing edge of the upper echo interface to the leading edge of the lower echo interface, and excludes the width of both echo interfaces. (3) The leading-leading method measures thickness from the leading edge of the upper echo interface to the leading edge of the lower echo interface, and includes the width of only the upper echo interface.

The 2-DE low- and high-gain images of the formalin-fixed cylinders of myocardium (Fig. 2) were traced using a wax pencil with a video overlay technique using 3 methods: (1) The inner edge method, which is the most commonly used, outlines the inner border of the circular echo image all along the circumference. (2) The leading edge method is shown by the broken line in Figure 2; at the point closest and farthest from the echo transducer corresponding to the central top and bottom of the circular echo image, the broken line is at the leading edge, but as the circle is followed toward its lateral margins, the broken line is drawn toward the center of the echo signature. (3) A mid-echo method follows the center of the echo width along the entire circumference. Cross-sectional areas were determined from the circular tracings by means of planimetry. Both the echo transducer and the objects were in fixed positions during the change of gains. Increasing gain was associated with receding trailing edges, blooming lateral edges, but stationary leading edges confirming the adequacy of a leading edge methodology just described and outlined in Figure 2. Although in vitro cylindrical wall thickness (<1 mm) is negligible with regard to 2-DE axial resolution, in vivo LV wall thickness (>5 mm) is substantial. Figure 3 demonstrates the appropriate in vivo tracing methods.

Comparison of 2-DE with direct in vitro measurements was performed by linear regression and percent error analyses of both thickness of myocardial section and area of myocardial cylinder. For each method, an average of duplicate measurements by 1 observer was compared with the in vitro measurement. Each individual percent error of measurement was calculated as follows: error (%) = direct − 2-DE/direct × 100. The average percent error was determined as the mean of the absolute individual error determinations, 8 for thickness (Fig. 3) and 4 for area (Fig. 4).

In vivo studies: Seven mongrel dogs (24 to 35 kg) were anesthetized with intramuscular morphine (1.5 mg/kg) and intravenous pentobarbital sodium (30 mg/kg). Respiration was maintained with room air using a Harvard respirator pump. Placement of catheters, 2-DE examination according to the method developed and extensively used in our laboratory, and cineventriculography were accomplished in this closed-chest preparation in the control state. Figure 3 shows a typical 2-DE systolic short-axis image at the mid-papillary level of an in vivo canine left ventricle with a demonstration of the tracing methods for endo- and epicardium.

Single-plane cineangiography was performed 5 to 10 minutes after 2-DE to eliminate differences in heart rate. The dog was placed on its left side in a right anterior oblique rotation.[12]

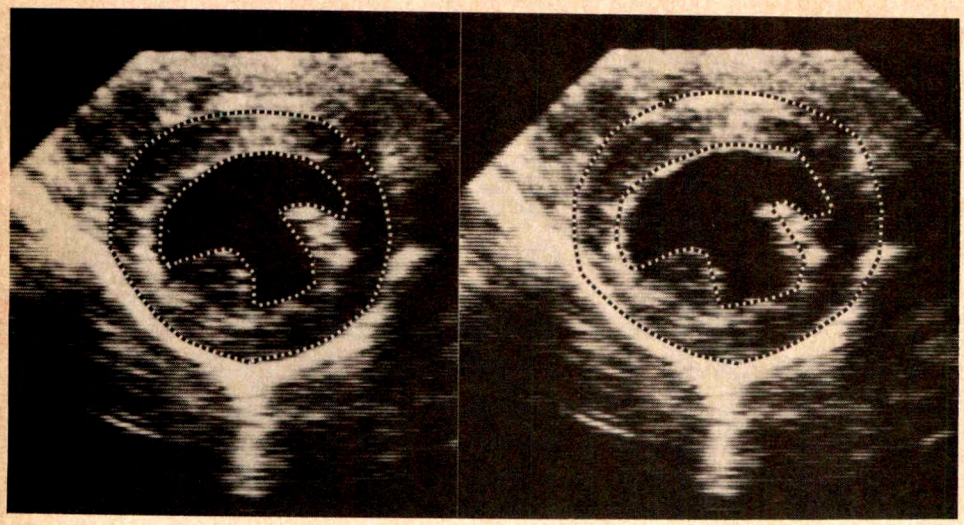

FIGURE 3. Typical 2-dimensional echocardiographic short-axis image of the mid-papillary level of the in vivo left ventricle of a closed-chest dog (at end-systole). **Broken lines** demonstrate the inner edge tracing method (**left**) and the leading edge tracing method (**right**).

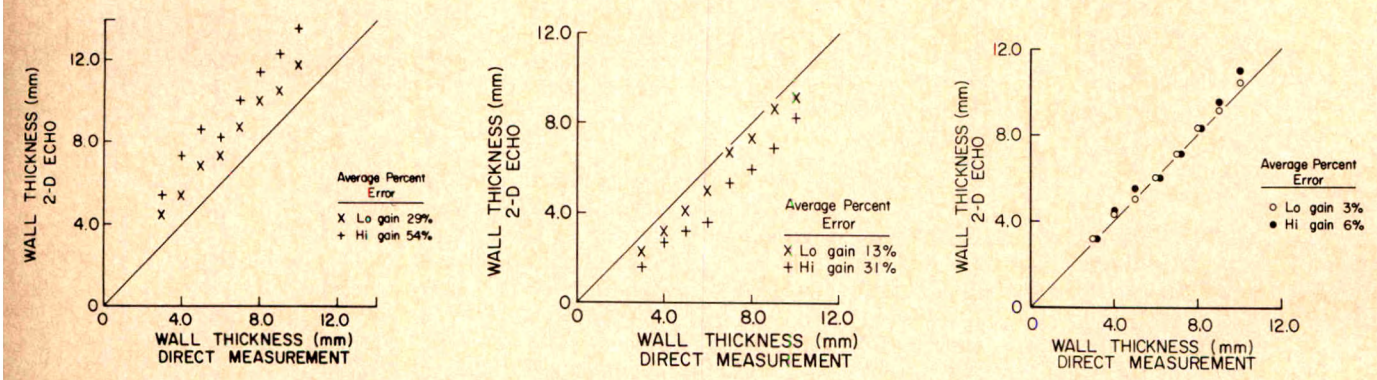

FIGURE 4. Comparison of in vitro myocardial thickness measurements, direct (x-axis) versus 2-dimensional echocardiography (2-D Echo) (y-axis) with (**left**) leading-trailing, (**middle**) trailing-leading, and (**right**) leading-leading methods in the presence of low gain (x or o) and high gain (+ or ●). Average percent errors are listed for low (Lo) and high (Hi) gains. The identity line is indicated by a **solid line.** Linear regression equations for the data are as follows: Lo gain (a) $y = 1.03x + 1.41$, (b) $y = 1.03x - 0.89$, $y = 1.02 + 0.23$; Hi gain (a) $y = 1.10x + 2.46$, (b) $y = 0.91x - 1.21$, (c) $y = 0.97x + 0.60$.

LV injection of 50% Hypaque® solution (1 ml/kg) was performed through a #7Fr pigtail catheter and synchronized with the electrocardiogram for early diastole. Ventriculograms were recorded at 30 frames/s on 16-mm film. The left ventricle was adequately opacified in all dogs at the time of the second or third beat after the start of injection. Outlines of the left ventricle were traced from the frame immediately preceding the onset of contraction, determined by visual comparison (end-diastolic volume), and the frame with the smallest intraluminal area, before opening of the mitral valve (end-systolic volume). LV volumes at both end-diastole and end-systole were computed using the standard formula, assuming geometry of an ellipsoid of revolution. This volume was corrected by means of the Bentivoglio regression equation.[12] No measurements were made during ectopic or postectopic beats.

Data analysis: For 2-DE LV volumes, both the Simpson and the 5/6 short-axis area multiplied by the length reconstruction formula[2,4] were used, and results were compared with determination of volumes by cineangiography. Linear regression analysis was performed using the least-squares method, and standard error of the estimate was calculated.

Reproducibility of echocardiographic measurements: In vitro myocardial thickness and cavity area measurements were performed by 2 trained observers who independently selected, traced, and measured their own frames from the audiovisual tape recording. Average percent error between the 2 observers was calculated separately for low- and high-gain settings.

Results

In vitro studies: Figure 4 shows plots for direct measurement of myocardial thickness on the x-axis versus 2-DE measurements of thickness on the y-axis for the 3 echocardiographic methods of measurement (see Methods section). For all 3 methods, linear regression analysis gave excellent correlation coefficients at low gain, 0.995 to 0.996, and only slightly lower results at high gain: 0.993 for leading-leading, 0.991 for trailing-leading, and 0.985 for leading-trailing. Average percent error of direct myocardial thickness determinations versus 2-DE measurements differed dramatically for these 3 methods (Fig. 4). Regression equations are listed in the legend. With the leading-trailing method (Fig. 4, left), 2-DE consistently overestimated myocardial thickness, all points lying above the identity

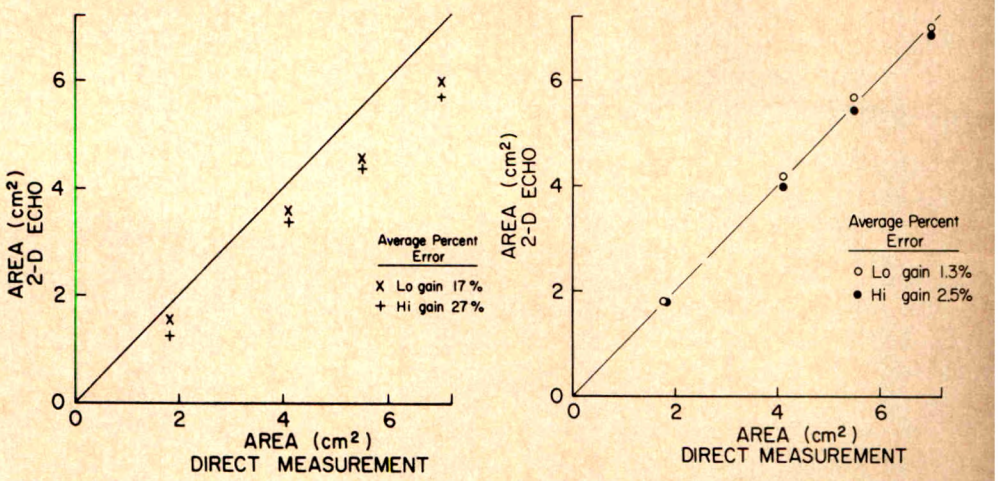

FIGURE 5. Comparison of in vitro myocardial cylindrical area measurements, direct (x-axis) versus 2-dimensional echocardiography (2D Echo): (**left**) inner edge and (**right**) leading edge methods in the presence of low gain (x or o) and high gain (+ or ●). Average percent errors are listed for low and high gains. The identity line is indicated by a **solid line.** Abbreviations are the same as in Figure 3. Linear regression equations for the data are as follows: Lo gain (a) $y = 0.87x - 0.18$, (b) $y = 0.99x - 0.18$; Hi gain (a) $y = 0.87x - 0.55$, (b) $y = 0.99x + 0.01$.

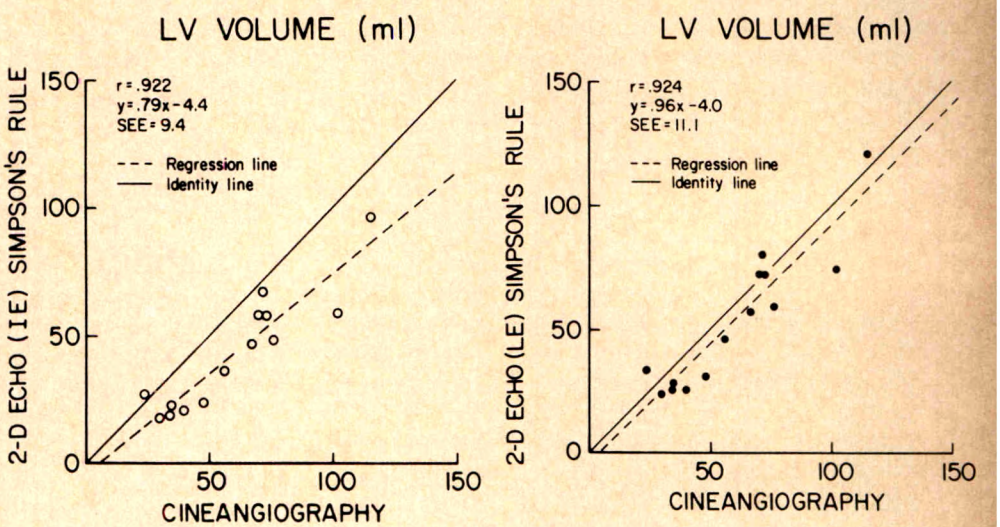

FIGURE 6. Comparison of left ventricular (LV) volume determinations, cineangiography (x-axis) versus 2-dimensional echocardiography (2-D Echo) (y-axis) with (**left**) inner edge (o) and (**right**) leading edge (o) methods. LV volumes were determined at end-diastole and end-systole by a Bentivoglio[12] regression equation for cineangiography. Linear regression analysis was performed; the correlation coefficient (r), regression equation, and standard error of estimate (SEE) are listed. Regression and identity lines are shown. IE = inner edge method; LE = leading edge method.

line. Average percent error calculation indicated a 29% overestimation for low gain and a much greater (54%) overestimation for the high-gain setting. With the trailing-leading method (Fig. 4, middle), 2-DE consistently underestimated myocardial thickness, all points lying below the identity line. Average percent error indicated a 13% underestimation for low gain and a 31% underestimation for the high-gain setting. In contrast, with the leading-leading edge method (Fig. 4, right), data points were distributed on or near the identity line and the average percent error was quite small, only 3% for the low-gain and 6% for the high-gain setting.

Figure 5 shows graphs similar to those in Figure 4 but involving measurements of cross-sectional cavity areas. Regression equations are listed in the legends. With the inner edge (trailing-leading) method (Fig. 5, left), points are distributed below and to the right of the identity line, indicating a consistent underestimation of cross-sectional area by 2-DE. Although the correlation coefficients are excellent, 0.988 for low and 0.999 for high gain, the average percent errors were quite high, 17 and 27%, respectively. In contrast, with the leading edge method (Fig. 5, right), points are distributed near and on either side of the identity line, indicating a close estimation of area by 2-DE. Computed correlation coefficients were 1.000 for the low-gain and 0.998 for the high-gain settings, and average percent errors were very low—1.3 and 2.5%, respectively. From the regression equations, one observes intercepts near 0 but slopes that are nearer 1.0 for the leading edge (0.99) than for the inner edge (0.87) method. Corresponding percent errors for the "mid-echo" method were 2.5% for the low-gain and 9.1% for the high-gain setting, whereas correlation coefficients were above 0.980.

In vivo studies: Figure 6 shows plots of LV volumes at end-diastole and at end-systole for 2-DE versus angiography in 7 dogs. 2-DE volumes were calculated by Simpson's rule for serial short-axis areas and length, the short-axis myocardial sections being traced by the inner edge (trailing-leading) method (Fig. 6, left) and leading edge method (Fig. 6, right). Linear regression analysis revealed good correlation coefficients of 0.92 for both methods and similar values for intercept and variability. However, the slope is substantially higher for leading edge (0.96 versus 0.79), similar to the in vitro cavity area slope comparison (0.99 versus 0.87). Examination of the

graphs shows that the use of inner edge methodology results in a greater and more consistent underestimation of LV volume than does the use of leading edge method; this difference is evident in the lower average percent error for leading edge (10 versus 17%).

Similarly, the LV short-axis area-length formula[2] gave good linear correlations (>0.860) for both tracing methods, but the inner edge method gave a greater, more consistent underestimation of volume than did leading edge method (12 versus 9%).

Interobserver reproducibility of echocardiographic measurements: For myocardial thickness measurements, slightly smaller average percent errors were observed with the leading-leading method (3 and 6% for low and high gains, respectively); values for other methods ranged up to 10%. For cavity area measurements, average percent errors were quite small, 2 and 3%, respectively, for both inner edge (trailing-leading edge) and leading edge methods. For 20 in vivo LV short-axis area measurements, average error between observers was not significantly different for leading and inner edge methods, 5.9 ± 0.9% versus 5.7 ± 1.4% (mean ± standard error of the mean), respectively.

Discussion

This study of quantitative 2-DE examines the accuracy of several methods of obtaining unidimensional and cross-sectional measurements. To obtain satisfactory direct tissue measurements, myocardium was sliced into appropriate frozen or formalin-fixed sections. The use of sliced myocardium with smooth, regular surfaces was required to facilitate precise and direct measurement and also to avoid errors encountered when attempting to rationalize the location of the echo beam in tissue with irregular surfaces. Thin myocardium (<1 mm thick) was applied for constructing precise cylinders with a single interface in the echo image, avoiding complications resulting from double interfaces. With this in vitro approach, only a leading edge 2-DE measurement method provided consistent accurate estimation of thickness and cavity area at both low- and high-gain settings (1.3 to 6.0% error). Other commonly used echocardiographic methods of measuring myocardial thickness resulted in either substantial overestimations (leading-trailing or standard convention) or understimations (trailing-leading or Penn convention). Leading edge area measurements showed low percent errors despite the fact that some arbitrary judgment was required in estimating the leading edge crossover in the lateral portions of the circle (Fig. 2); interobserver variability was only about 6%. The commonly used inner edge (trailing-leading) echo method for cross-sectional area measurement consistently underestimated the direct area measurement.

The features of a 2-DE short-axis image of the left ventricle may vary substantially, depending on the type of echo machine used and the gain settings. The difference between leading edge and inner edge delineations would tend to be greater in images with broader echo interfaces. Garcia et al[13] previously described computerized algorithms for performing correction from the conventional inner edge (trailing-leading) to the leading edge method for delineation of endocardial borders in 2DE short-axis images.

Previous studies with M-mode echocardiography showed that reasonably good estimations of LV mass can be obtained with wall thickness being measured by leading-trailing or trailing-leading methods.[14–16] Because wall thickness varies widely throughout the left ventricle, only an average wall thickness is required for calculating LV mass. Consequently, a good estimation of mass does not necessarily imply accurate measurements of wall thickness. Devereux and Reichek[14] stated that even though the trailing-leading method gave the best estimate of average wall thickness for LV mass determination, it could not be judged whether it was due to increased accuracy of measurement or just fortuitous compensation of factors.

Because the endocardial surface of the beating heart is not smooth, but highly irregular because of trabeculae and papillary muscles, practical application of the leading edge method might not be as simple as that with in vitro smooth surface objects. To investigate this problem, LV volume was determined by 2-DE in 7 dogs and compared with LV volume obtained by cineangiography. Previous studies in the beating heart have shown good correlations but consistent volume underestimation[6,8,10] with a 2-DE inner edge method. In the current study, similar observations were made in 7 dogs, but additional observations with a 2-DE leading edge method indicated consistently closer estimations of angiographic LV volume than those with inner edge method. For leading edge versus inner edge method, regression slopes were nearer 1.0 with both in vitro cavity area (0.99 versus 0.87) and in vivo LV volume (0.96 versus 0.79), whereas correlation coefficients, intercepts, and variability were similar for the 2 methods. Although cineangiography as an indirect method for estimating LV volume does not provide a perfect reference standard,[17] the consistency of results from in vitro to in vivo phases of the current study suggests the adequacy of angiography as a reference standard for LV volume and tends to confirm the superior adequacy of the leading edge method for in vivo as well as in vitro applications. The small 2-DE underestimation of angiographic LV volume with the leading edge method might be attributed to inherent differences between angiographic and echocardiographic techniques.[17] First, injection of contrast material may increase actual LV volume during cineangiography. Second, LV endocardial image projection with 2-DE may represent the surface of trabeculae, whereas in cineangiography a deeper silhouette contour may be imaged because contrast material enters the spaces between the trabeculae. For these reasons, LV volume estimation by cineangiography would be expected to slightly exceed that of 2-DE. Bommer et al,[18] using directly measured volume standards, recently demonstrated that estimations of volume by angiography and 2-DE are comparably accurate.

Correlation coefficients for angiographic versus echocardiographic comparisons in this study were quite close to those observed in a previous study (r = 0.92 for Simpson's rule, r = 0.87 for the bullet formula).[6] Thus,

the leading edge method may be well suited for LV volume determination from 2-DE images of the beating heart, in which the endocardial surface is quite irregular. This observation may be due to the averaging effect in determining LV volumes from short-axis areas. However, precise 2-DE measurement of wall thickness at any given point in the LV wall may be complicated by irregularities in the LV endocardial surface.

In summary, study of ultrasonic images obtained with 2-DE indicates that a leading-to-leading edge method may be most accurate for linear and cross-sectional measurements of the heart and also for LV volume determination.

Acknowledgment: We thank Myles Prevost for his technical assistance, Mark Koury and Joye Nunn for typing the manuscript, and Lance Laforteza for graphic illustrations. We also thank Jeanne Bloom for her editorial assistance.

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal.* All accepted manuscripts are subject to editing to aid understanding and conserve space.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

TITLE PAGE, SUMMARY, AND ABSTRACT: Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

REFERENCES: In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

Journal: Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.

Chapter in Book: Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.

Book: Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

FIGURES: Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

TABLES: Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present, a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

REPRINTS: Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.

PaceLetter®

A TECHNOLOGY UPDATE

1

Pacemaker Telemetry: Luxury or necessity?

It's been around for barely four years. In fact, we introduced a form of it, ten years ago. Since that time, it has been refined and expanded. And virtually all pacemaker manufacturers have added it to their technology.

It is *telemetry*, and despite being one of the most important tools at a physician's disposal, it is largely misunderstood. Why?

To begin with, education about telemetry and its uses has not kept pace with the development of the technology itself. And, differing terminology has further confused what telemetry is, and what its various types are.

A *complete* telemetry system, such as that found in Pacesetter's Programalith® series, provides *stored*, *programmed* and *measured* data. This allows you to determine what the implanted unit *is*, what it *should* be doing, and what it is *actually* doing. *All non-invasively*.

Together, the three types of telemetry answer the three basic questions:

- What is the implanted unit?
- Is it working properly?
- How long will it last?

In short, the presence of stored, programmed and measured telemetry enables the physician to make a complete analysis not available in any other way. In fact, appropriate diagnosis and prescription may be virtually impossible *without* the data that modern telemetry provides.

So, the question arises: is the presence of telemetry a luxury, or a necessity?

Programalith A-V | Programalith II | Programalith III

To assist you, Pacesetter Systems, Inc. has prepared a detailed technical paper on how to use this vitally important technology. Write for it. Read it.

And then you decide.

Writing with care for CHF:

Avoid any change in the classic digitalis-Lasix® regimen.

BRAND OF (furosemide)

9 out of 10 cardiologists specify LASIX® (furosemide) by brand name.* And 2 out of 3 take the extra step to prevent substitution.*

7 out of 10 cardiologists also specify the leading brand of digoxin.* Both are part of the classic LASIX®-digitalis regimen.

In the same survey,* LASIX® and the leading brand of digoxin were named more often than any other agent, in any therapeutic class, as drugs for which these cardiologists would *never* allow generic substitution. Both were prescribed by brand name more often than any other drug.

LASIX®—specified for good reason.

Especially in CHF, precision is crucial. Any therapeutic variable could easily upset the sensitive digitalis/diuretic/electrolyte balance and precipitate digitalis toxicity.

LASIX®, the most thoroughly documented drug in its class, offers quality so consistent that almost 8 billion tablets have been manufactured without a single product recall. In more dosage strengths and forms than any other diuretic. Good reason for the cardiologists surveyed to say they prescribe LASIX® more frequently than all other diuretic agents they named.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

*National survey of 2960 physicians, including 1502 cardiologists and other physicians subspecializing in cardiology, conducted by Hoechst-Roussel Pharmaceuticals Incorporated, Somerville, New Jersey. August, 1982.

The diuretic of choice in CHF.

LASIX®

20 mg
40 mg
80 mg
Tablets

BRAND OF (FUROSEMIDE)

Rx

Specify LASIX® brand of furosemide. To be sure the patient receives only LASIX®, take the steps necessary on your prescription to prevent substitution, in accordance with the regulations of your state.

Lasix 40mg #60
Sig. i b.i.d.
Do Not Substitute

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion: this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

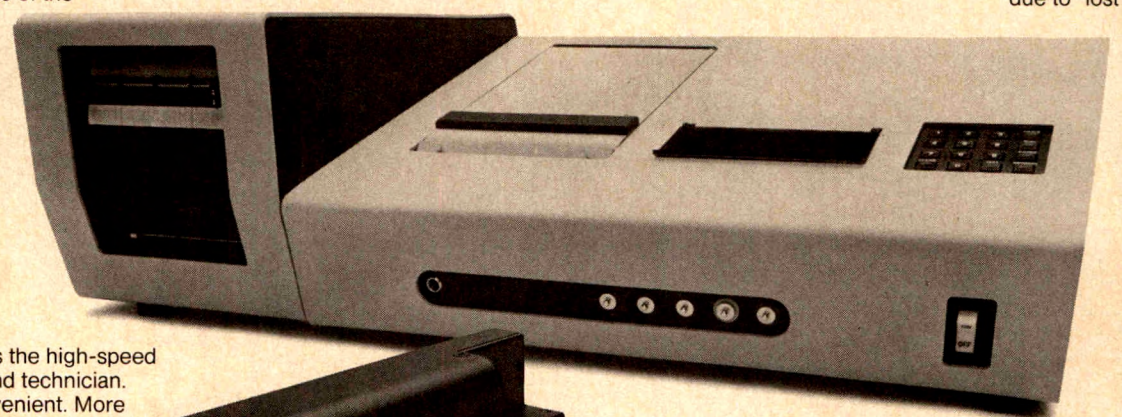
Clinical evaluation of various systems for analysis of ambulatory ECG records has been difficult to implement due to the variety of approaches to recording data, the operator-dependence of traditional recording and interpretation systems, and the subjective clinical judgements necessary in using the final results. One manufacturer can now report data utilizing a real-time approach to ambulatory monitoring that compares clinical accuracy to hand-counted data as a standard.[1]

In Holter studies, AEGIS™ gives you results in minutes... right in your office... without a specially trained operator.

- Provides the same clinical information as a scanning service—with none of the drawbacks.
- Fits easily into any office.
- System validates itself—no need for repeat studies due to "lost" data or faulty equipment



- Replaces the high-speed scanner and technician. More convenient. More efficient.
- Puts the control of evaluating Holter studies directly into your hands. Provides time-stamped rhythm strip and summary report for your confirmation.

- Analyzes each heartbeat as it occurs; counts and categorizes arrhythmias in real time.

For a 15-minute, no obligation demonstration, call toll-free: 800-257-5750.

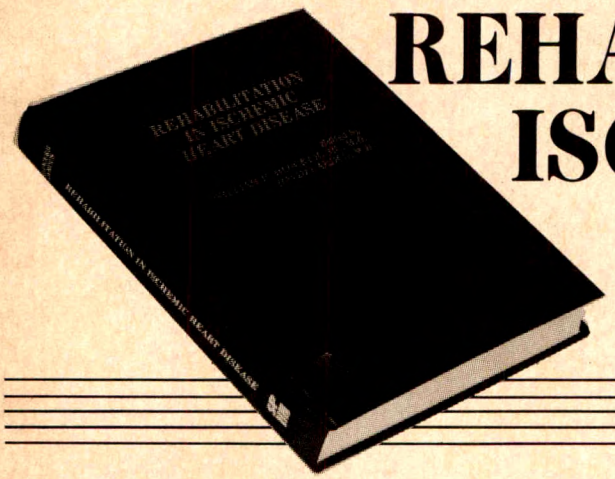
REHABILITATION IN ISCHEMIC HEART DISEASE



Approx. 500 pp., 188 figs. & tbls., large format 8½x11, 1982, $80.00

Edited by **William P. Blocker, Jr., M.D.,** F.A.C.P., Chief, Rehabilitation Medicine Service, V.A. Hospital, Houston, Assistant Professor of Physical Medicine, Baylor College of Medicine, Houston, and **David Cardus**, M.D., F.A.C.C., Professor of Physiology and Rehabilitation, Baylor College of Medicine, Houston, Texas.

Heavily illustrated, this volume presents 60 self-contained chapters dealing with *all* aspects of rehabilitation of the patient with ischemic heart disease. The 45 noted contributors discuss topics such as: designing a cardiac rehabilitation center; methods of rehabilitation for the stroke patient, amputee, spinal cord injury patient who has had a heart attack; equipment needs for a cardiac rehabilitation center; and legal responsibilities of the physicians and therapists.

All major aspects, from epidemiology and pathogenesis through prevention and education are covered, including ambulatory monitoring of electrocardiogram and blood pressure; evaluation of degree of disability; and pathogenesis of atherosclerosis. This book contains the *most complete* list of cardiac risk factors to be found in any text. This encyclopedic guide to the total care and rehabilitation of cardiac patients is written for *every* member of the cardiac rehabilitation team.

CONTENTS

PREFACE

PART I. EPIDEMIOLOGICAL ASPECTS 1. Statistical Studies: *William P. Blocker, Jr., M.D.* **2.** Coronary Risk Factors: *William P. Blocker, Jr., M.D.* **3.** Socioeconomic Factors: *Eleanor H. Kyle*

PART II. PATHOGENIC ASPECTS 4. Pathogenesis of Atherosclerosis: *Russell Ross, Ph.D., and John A. Glomset, M.D.* **5.** Biochemical Manifestations of Ischemic Heart Disease: *Mark Entman, M.D., and Jeanie McMillin-Wood, Ph.D.* **6.** Pathophysiology of Ischemic Heart Disease: *Robert A. Chahine, M.D.*

PART III. CLINICAL ASPECTS 7. The Natural History Of Ischemic Heart Disease: *David Cardus, M.D.* **8.** Clinical Manifestations of Ischemic Heart Disease: *Don W. Chapman, M.D., W. Richard Cashion, M.D., James C. Costin, M.D., and William H. Spencer, III, M.D.* **9.** Complications of Ischemic Heart Disease: *William P. Blocker, Jr., M.D.*

PART IV. EVALUATIVE ASPECTS 10. Anatomy and Angiography of Coronary Vessels: *Paul K. Peterson, M.D.* **11.** Exercise-Stress Testing in Ischemic Heart Disease: *David Cardus, M.D.* **12.** Myocardial Imaging: *Arnold Nitishin, M.D.* **13.** Disability Evaluation of the Cardiac Patient: *William P. Blocker, Jr., M.D.* **14.** Assessment of Obesity in the Cardiac Patient: *David Cardus, M.D., and William P. Blocker, Jr., M.D.*

PART V. MANAGEMENT ASPECTS 15. Evolution of the Treatment and Rehabilitation of the Cardiac Patient: *William P. Blocker, Jr., M.D. and Martin Grabois, M.D.* **16.** Treatment of the Acute Myocardial Infarction and its Complications: *Frank G. Yanowitz, M.D.* **17.** Rationale for Cardiac Rehabilitation: *William P. Blocker, Jr., M.D.* **18.** A Blueprint for Cardiac Rehabilitation: *William P. Blocker, Jr., M.D.* **19.** Patient Selection for a Cardiac Rehabilitation Program: *William P. Blocker, Jr., M.D.* **20.** Stage I of Cardiac Rehabilitation: Acute Phase of Cardiac Rehabilitation: *William P. Blocker, Jr., M.D.* **21.** Rehabilitation Phase Home Cardiac Rehabilitation Program (Stage II): *Henry J. Ostermann* **22.** Stage III of Cardiac Rehabilitation: Cardiac Rehabilitation Ward Program: *William P. Blocker, Jr., M.D.* **23.** Stage IV of Cardiac Rehabilitation: Recovery and Outpatient Follow-up Program: *G. Harley Hartung, Ph.D., and Claude R. Youngblood, M.A.* **24.** Implementing the Exercise Prescription: *David Cardus, M.D.* **25.** Prescription for Cardiac Rehabilitation Program: *G. Harley Hartung, Ph.D.* **26.** Monitoring of the Cardiac Rehabilitation Program by Electrocardiogram Telemetry: *Robert W. Dahl* **27.** Electrocardiogram Monitoring During Exercise and Factors Influencing its Interpretation: *Liep Hian Tjeng, M.D.* **28.** Electrocardiographic and Blood Pressure Ambulatory Monitoring: *William P. Blocker, Jr., M.D.* **30.** Cardiopulmonary Resusitation: *Albert E. Raizner, M.D.* **31.** Myocardial Revascularization in Cardiac Rehabilitation: *Gene A. Guinn, M.D. and Virendra S. Mathur, M.D.* **32.** Rehabilitation Following Cardiac Surgery: *William P. Blocker, Jr., M.D.* **33.** Management of the Myocardial Infarctions. Patient with Most Commonly Associated Diseases: *William P. Blocker, Jr., M.D.* **34.** Cardiac Rehabilitation of the Physically Handicapped (Amputee, Hemiplegic, Spinal Cord Injury Patient, and Obese Patient) *William P. Blocker, Jr., M.D., and Vincent Kitowski, M.D.* **35.** Rehabilitation Exercise Programs for the Older Disabled: *William P. Blocker, Jr., M.D., G. Harley Hartung, Ph.D., and Robert L. Payne, Jr.* **36.** Sexual Activities and the Coronary Patient: *Kenneth F. Kopel, Ph.D.* **37.** Biofeedback for Heartrate Control: *Sidney E. Cleveland, Ph.D., Paul Baer, Ph.D., and Keith Revel, M.A.* **38.** The Role of the Nurse in the Cardiac Patient's Rehabilitatio *Margaret Edwards, R.N., Rosetta Thompson, R.N., Christe S. McGinley, R.N., Leticia Corpus, R.N., and Joan Seidel, R.* **39.** The Role of the Physical Therapist in Cardiac Rehabilit tion: *Mary Ida Key, R.P.T.* **40.** The Role of the Occupation Therapist in Cardiac Rehabilitation: *Elinor C. Thornberr O.T.R., and M. Hope Kenney, O.T.R.* **41.** The Role of the E ercise Physiologist in Cardiac Rehabilitation: *G. Harley Ha tung, Ph.D.* **42.** The Role of the Dietician in Cardi Rehabilitation: *Mary L. Currently available antianginal agents...
and how they are most appropriately employed as

BASIC THERAPY FOR THE PREVENTION OF ANGINA PECTORIS*

Report from "Step-Care Therapy for Ischemic Heart Disease"
—a special symposium preceding the annual meeting
of the American College of Cardiology, April 24, 1982.

Synopsis of the Symposium

Step 1: Nitrates

Since nitrates both reduce myocardial oxygen demand and increase myocardial oxygen supply, their use is warranted as initial therapy for the control of angina pectoris. Dosage needs often vary significantly from patient to patient, and attention should be given to ensure that an adequate dosage level has been established.

Step 2: Nitrates and beta blockers

For angina refractory to maximum-dose nitrate therapy, the complementary actions of beta blockers and nitrates provide a rational therapeutic modality. At this point a beta blocker should be added to the nitrate regimen.

Step 3: Nitrates and calcium antagonists

Calcium antagonists have special usefulness in controlling cases where the myocardial oxygen supply is diminished by coronary vasospasm; their use in combination with nitrates is recommended if Step 2 therapy is unsatisfactory (or if the patient has variant or vasospastic angina).

Consensus of the Symposium

Nitrates are basic in step-care therapy for ischemic heart disease

Step 1
Stable or unstable angina: Nitrates

Step 2
If not controlled: Nitrates + beta blockers

Step 3
If still not controlled (or in variant angina): Nitrates + calcium antagonists

The basic antianginal agent in these basic dosage forms

ISORDIL® SUBLINGUAL
Sublingual Tablets, 2.5 mg, 5 mg, and 10 mg

ISORDIL® CHEWABLE
Chewable Tablets, 10 mg

ISORDIL® TITRADOSE®†
Oral Tablets with E.Z. Split® scoring: 5 mg, 10 mg, 20 mg, and 30 mg

ISORDIL® TEMBIDS® Capsules
Sustained-Release Capsules, 40 mg

TEMBIDS® — TRADEMARK FOR SUSTAINED-RELEASE CAPSULES
†US Pat Nos 3883647 and D224591 (Titradose®)

In angina pectoris...

ISORDIL® (ISOSORBIDE DINITRATE)

is basic

*ISORDIL has been evaluated as probably effective when taken by the sublingual or chewable route and possibly effective when taken orally for this indication. See Brief Summary on following page.

Ives®

© 1982 Ives Laboratories Inc.

ISORDIL®
(ISOSORBIDE DINITRATE) IS BASIC

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: When taken by the sublingual or chewable route, Isordil Sublingual and Chewable Tablets are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.
Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.
Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.
Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

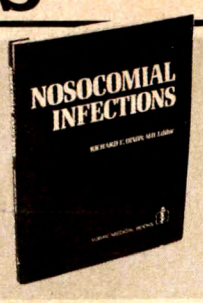
appx. 344p June 1981,
$29.50 hardbound
ISBN 0-914316-24-9
$19.50 softbound
ISBN 0-914316-29-X



Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Center for Disease Control, this book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years. This major reference is divided into 11 sections consisting of 50 chapters written by over 100 internationally known experts.

The book includes:

- An update of disease trends since the 1st International Conference held a decade earlier
- New information on the efficacy of specific approaches to infection control
- Discussions on how to implement effective infection surveillance and control programs
- Coverage of the increasing importance of antimicrobial resistance of nosocomial pathogens
- Information on the potential usefulness of antimicrobial prophylaxis in selected patient groups

and many other topics.

The First Human Heart Defibrillation

LESLIE A. GEDDES and ROBERT HAMLIN

In 1947, Beck et al[1] reported the first successful defibrillation of the human heart. Stating that "ventricular fibrillation occurs as a terminal arrhythmia in 50 percent of patients" (citing a paper that they were preparing), they continued, "If ventricular fibrillation develops in hearts that are relatively normal, especially during operation, defibrillation may be lifesaving." In 1937, Beck and Mautz[2] reported the development of this technique in dogs, in which defibrillation had been accomplished after 30 minutes of open-chest cardiac massage and artificial respiration.

The opportunity for the human application occurred in association with a 14-year-old boy who had been admitted for sternal resection. Beck wrote:

> During the induction of the nitrous oxide and ether anesthesia, on the sixth hospital day, the pulse rate rose to 160 per minute and remained at this level for forty-five minutes. After the administration of 1.6 mg. of lanatoside C the rate returned to 80 per minute, where it remained during most of the two hours required for completion of the operation. There were no other unusual circumstances attending the procedure.
>
> During the closure of the wound in the chest, the pulse suddenly stopped and the blood pressure sounds could not be heard. The patient was apparently dead.

From the Institute for Interdisciplinary Engineering Studies, Biomedical Engineering Center, Purdue University, West Lafayette, Indiana. Manuscript received February 7, 1983, accepted April 29, 1983.

Address for reprints: L. A. Geddes, ME, PhD, Institute for Interdisciplinary Engineering Studies, A. A. Potter Engineering Center, Purdue University, West Lafayette, Indiana 47907.

The wound was reopened and cardiac massage immediately was initiated, 1 mg. of epinephrine given intravenously and more lanatoside C administered with no visible or responsive effects. The mechanical respirator was attached to the intra-tracheal tube and cardiac massage continuously given for the next thirty-five minutes, at the end of which time the electrocardiogram (fig 1a) was characteristic of ventricular fibrillation. Another record ten minutes later was recorded just prior to the first electric shock applied directly to the heart (fig 1b). This record, as well as the tracing recorded immediately after the first shock, also showed ventricular fibrillation. Since the first shock was unsuccessful, procaine hydrochloride was injected into the right auricle, the heart massaged and a second series of shocks given. The heart then was in standstill.

Almost immediately, however, feeble, regular and fairly rapid cardiac contractions were seen, but massage was continued for five more minutes, at which time it was obvious that contractions were coordinated and fairly vigorous, though still fast. An electrocardiogram taken at this time revealed a supraventricular tachycardia at a rate of 175 (fig 1c). From this point on the heart gradually increased in vigor and brachial sounds were heard at 50 mm. of mercury. It is of more than passing interest to note that in spite of the critical condition of the patient and the apparent hopelessness of the situation, at no time was cyanosis or pupillary dilation present. This demonstrates that massage of the heart had maintained an adequate circulation.

After the coordinated heart beat had been established for twenty minutes, the wound in the chest was closed. Within ten minutes after closure of the wound the intra-tracheal tube was removed and respirations were

resumed. Within one and one-half hours the blood pressure rose to 60 systolic and 40 diastolic, and thereafter it showed a steady, gradual rise to 100 systolic and 70 diastolic. Three hours after defibrillation of the ventricles, the patient responded rationally to questioning, and by eight hours he was fairly alert in spite of his stormy operation course.

The convalescence for the next few days was chiefly characterized by signs of digitalis intoxication and moderately severe azotemia, the nonprotein nitrogen reaching 100 mg. per hundred cubic centimeters on the second postoperative day. Within eight days, however, the patient was much improved, digitalis induced coupling having disappeared and the blood urea nitrogen having returned to 18 mg. per hundred cubic centimeters.

During the remaining seventeen hospital days, there were no symptoms or signs indicative of injury to the central nervous system, and he was discharged on his thirty-first hospital day. In a follow-up interview three months later, the patient stated that he had considerable increase in exercise tolerance. Electrocardiographic tracings at this time were normal (fig 2).

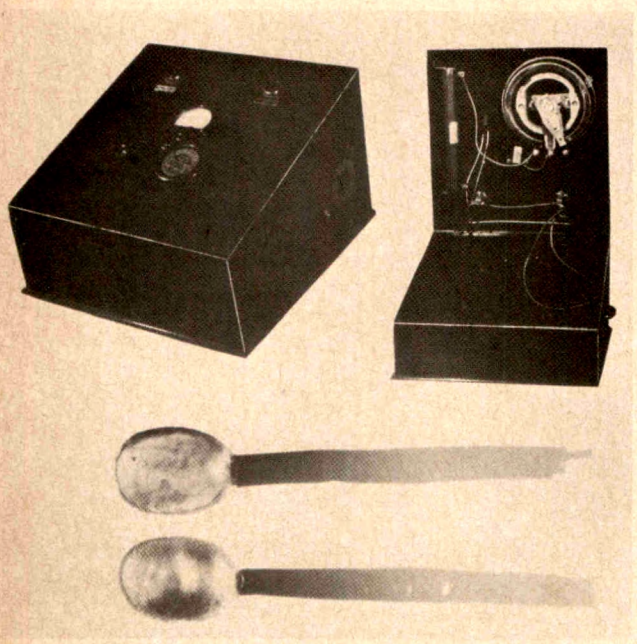

FIGURE 3. Beck's defibrillator with cover closed (**top left**) and open (**top right**); **bottom,** the electrodes, which were stored in the defibrillator cabinet.

Beck's prescription for defibrillation derived from his 1937 dog studies. He recommended: "An electrode preferably of silver, measuring about 25 square cm in area is placed on each side of the heart and an electric current is sent through the ventricles. The electrodes need not be padded to prevent burning if there is a large area of contact with the heart. The current is ordinary alternating current of 60 cycles and 1 to 1.5 amperes. The duration of the current is short, from 0.5 to about 2 seconds."

The defibrillator: Figure 3 is a photograph of Beck's defibrillator and electrodes, which were built by a friend, James Rand, an electrical engineer. The circuit diagram is shown in Figure 4 and reveals that the defibrillator consisted of an off-on switch, 2 pilot lights, a 10-ohm current-limiting resistor, a 25-ohm variable resistor (to enable setting the current), and a 0 to 5 ampere meter to indicate the current passing through the heart.

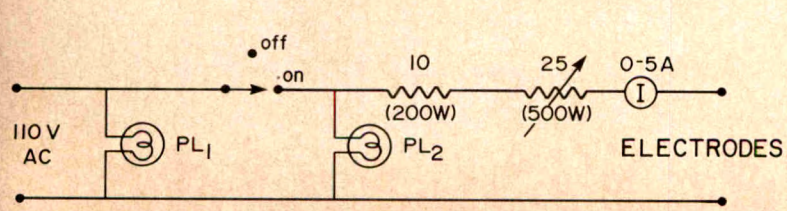

FIGURE 4. Circuit diagram of Beck's defibrillator which consisted of an off-on switch, 2 pilot lights, a 10-ohm current-limiting resistor, a 25-ohm variable resistor (to enable setting the current), and a 0 to 5-ampere meter (to indicate the current flowing through the heart).

With 28 ohms as a typical value of human heart resistance (Kerber et al[3] 1980), it is possible to estimate the typical maximum and minimum current that Beck could have used, which was as much as 2.8 or as little as 1.7 amperes. The corresponding energy values for a current flow of 0.5 second are 109 and 40 joules. Not long after, it was found that a current flow of about 0.2 second was adequate for defibrillation, thereby reducing the delivered energy by 60%.

So much interest was evidenced in Beck's success that he presented a monthly course on defibrillation during the years 1948, 1949, and 1950. On each of these occasions, some 2 dozen trainees fibrillated, massaged, and defibrillated the heart of a dog. The dog was recovered and presented to the class the next day.

Beck's defibrillator was duplicated by many investigators. Nine years later Zoll et al[4] used one with a higher output to accomplish closed-chest defibrillation. For the next decade alternating current was used and was displaced only when it was discovered that a single pulse of current could achieve defibrillation with the delivery of considerably less energy.

Ratio of Regurgitant Volume to End-Diastolic Volume: A Major Determinant of Ventricular Response to Surgical Correction of Chronic Volume Overload

HERBERT J. LEVINE, MD, and WILLIAM H. GAASCH, MD

A most difficult decision in the management of patients with left ventricular (LV) chronic volume overload is when to proceed with valve replacement. There is, of course, a natural reluctance for clinicians to urge open heart surgery in asymptomatic or minimally symptomatic patients, yet among some patients with chronic aortic regurgitation (AR) or mital regurgitation waiting for clear symptoms of pulmonary venous congestion or a convincing effort syndrome may result in a disappointing response to corrective surgery. Symptomatic patients who survive operation without important perioperative complications (infection, thromboembolism, paravalvular leak, and so on) generally are fully or partially relieved of their symptoms. In asymptomatic as well as symptomatic patients, improvement or benefit can also be measured objectively (that is, reduction in heart size, regression of hypertrophy, improvement in exercise tolerance and ventricular function, and improved survival). In some patients, regardless of whether symptoms have improved, LV size and myocardial mass do not decrease significantly. These patients have a less good prognosis[1–4] and a considerable effort has been made to establish preoperative criteria for identifying this cohort of patients before surgery is performed.

The following preoperative markers of a suboptimal response to valve replacement in chronic AR have been suggested: (1) a large end-diastolic volume,[3,5,6] (2) a large end-systolic volume,[2,4,7–9] (3) an elevated end-diastolic pressure,[1,10] (4) a subnormal ejection fraction,[7–9,11–14] (5) increased indexes of systolic wall stress,[2,4,15] and (6) reduced exercise capacity.[16] Although some of these indexes are better than others in predicting the outcome of corrective surgery in patients with chronic AR, it remains difficult to identify with certainty the patients whose ventricular mass and dimensions will fail to diminish postoperatively.

Despite an extensive and varied approach to this problem, relatively little attention has been given to the magnitude of the regurgitant volume itself. Indeed, the regurgitant leak *is* the basis for both the hemodynamic abnormality and the clinical syndrome of valvular regurgitation, and elimination of the regurgitant volume is the primary effect of successful valve replacement. Thus, there is reason to believe that a quantitative assessment of the regurgitant volume may be helpful in predicting the response to valve replacement of a given patient with chronic valvular regurgitation. However, efforts to measure regurgitant volumes accurately have been thwarted by serious limitations in methods, and perhaps the inability to quantitate regurgitant flow with confidence has obscured the importance of this measurement. Nonetheless, with better techniques for measuring regurgitant volume, our ability to predict the response of the ventricle to valve replacement may be greatly improved.

An example of the importance of the absolute size of the regurgitant volume and its relation to the end-diastolic volume is illustrated in Table I. Consider 2 patients with symptomatic chronic AR. Both have the same heart rate, blood pressure, LV diastolic pressure and aortic valvular lesion (that is, same regurgitant valve orifice). One patient, however, has a slightly enlarged left ventricle with normal ventricular function; the other has a dilated myopathic ventricle. To simplify the comparison, both patients will be assigned the same total stroke volume (TSV) and regurgitant fraction (regurgitant fraction = regurgitant volume/total stroke volume).

In both patients, the magnitude of the regurgitant leak is the same, although ventricular size and function differ greatly. After successful aortic valve replacement,

From The Department of Medicine, Tufts University School of Medicine, The New England Medical Center Hospital and the Veterans Administration Medical Center, Boston, Massachusetts. Manuscript received January 12, 1983; revised manuscript received April 25, 1983, accepted May 10, 1983.

Address for reprints: Herbert J. Levine, MD, New England Medical Center Hospital, 171 Harrison Avenue, Boston, Massachusetts 02111.

TABLE I Relative Volumes in Aortic Regurgitation

	Groups	
	A	B
End-diastolic volume index (EDVI) (ml/m^2)	100	200
Systolic ejection fraction	0.60	0.30
Total stroke index (ml/m^2)	60	60
Regurgitant fraction	0.50	0.50
Regurgitant stroke index (ml/m^2)	30	30
Regurgitant volume/end-diastolic volume	0.30	0.15
Postoperative EDVI (ml/m^2)	70	170

the regurgitant flow will be eliminated in both patients. Diastolic filling of the left ventricle will thus be reduced in both by an amount equal to the regurgitant stroke index (30 ml/m^2). Therefore, postoperative end-diastolic volume index (EDVI) in 1 (Group A patient) would be expected to be 70 ml/m^2, a reduction of 30%, whereas postoperative EDVI in patient 2 (Group B patient) will be 170 ml/m^2, a reduction of only 15%. Furthermore, because the fractional reduction in heart size will be less in the Group B patient, the "stimulus" to regression of hypertrophy also will be less, since wall stress is a linear function of chamber radius. The effect of eliminating regurgitant flow on LV filling pressure in both patients will be more difficult to predict, because the pressure-volume characteristics of the 2 ventricles certainly will be different. Nonetheless, because chamber compliance of the smaller ventricle will probably be less, the decrease in LV filling pressure will be proportionately less in the larger ventricle.

It is suggested, therefore, that the proportional reduction in heart size after aortic valve replacement is predicted by the ratio of regurgitant volume to end-diastolic volume. The implication of this assumption is that for a given amount of AR, the postoperative reduction in LV size and mass will be an inverse function of the end-diastolic volume. Not implicit in this analysis is that whereas regurgitant and end-diastolic volumes are "related" to one another, the end-diastolic volume of the ventricle has no *direct* influence on the size of the regurgitant volume.

Central to this issue is a clear understanding of the hemodynamic determinants of aortic regurgitant flow. As with turbulent flow across any orifice, pressure-flow relations across the aortic valve in diastole are defined by the Torricelli equation; that is, flow is proportional to the square root of the pressure gradient existing across the valve. Thus, the orifice equation, devised by Gorlin and Gorlin in 1951,[17] may be used to dissect the hydraulic factors that determine the regurgitant volume of a given lesion.

Determinants of aortic regurgitant volume: In the case of aortic valvular regurgitation, solving the orifice equation for aortic regurgitant stroke volume (ARV, ml) yields: $ARV = OA \cdot C \cdot Time_d \cdot \sqrt{P_1 - P_2}$, where OA = aortic regurgitant orifice area (cm^2), P_1 = aortic diastolic mean pressure (mm Hg), P_2 = LV diastolic mean pressure (mm Hg), $time_d$ = duration of diastole/beat (seconds), and C = constant.

There are, therefore, only 4 determinants of ARV: the size of the aortic valve orifice during diastole, the duration of diastole per beat (a function primarily of the heart rate) and the pressure in the aorta and left ventricle during diastole. Neither the forward stroke volume (or effective cardiac output) nor the size of the LV chamber have a *direct* bearing on ARV. It follows, therefore, that a large LV chamber does not mean that the regurgitant volume will be large. Indeed, under most circumstances, active enlargement of the ventricle is associated with an increase in filling pressures which would decrease rather than increase ARV.

Physiologic or pharmacologic manipulation of the constituents of the orifice equation, of course, will change regurgitant flow. For example, an increase in heart rate will reduce ARV by shortening diastole. Similarly, a venodilator that reduces left atrial and LV diastolic pressures more than it does arterial blood pressure can increase aortic regurgitant flow.

In addition to the primary determinants of regurgitant flow, each may be influenced secondarily by other hemodynamic variables. Changes in systemic vascular resistance, for example, may alter arterial diastolic pressure and, thereby, induce changes in ARV. Chamber volume, although not a primary determinant of regurgitant flow, will exert a secondary influence. In AR, chamber compliance of the left ventricle, a function of ventricular volume, will play a role in determining diastolic pressure and thus influence the size of the regurgitant volume. However, this will be so only through the mechanism of an altered diastolic pressure, not by virtue of the LV size as such. The difference between the 2 patients with AR illustrated in Table I lies not with the size of the regurgitant volume itself, but with myocardial factors that emerge as a consequence of the regurgitant volume.

Thus, among patients with chronic AR, while LV volume does not directly determine regurgitant volume, the immediate response of the ventricle to surgical correction of regurgitation will be influenced in a major way by the volume of the ventricle. The importance of this "immediate response" to valve replacement has been shown by serial echocardiographic studies performed soon after surgery. In a prospective echocardiographic study of the effect of valve replacement in patients with chronic AR, we[4,15] found that patients who achieved a substantial reduction in ventricular dimensions postoperatively did so before the time of the early postoperative study (7 to 10 days after surgery); little further reduction in LV size occurred during the course of the next 12 months. Similar observations have been made by others.[7,18–20] Furthermore, patients who did not achieve a significant reduction in LV size during the postoperative period had a less favorable outlook.[1–4]

To examine the hypothesis that the ratio of regurgitant volume to end-diastolic volume (RGV/EDV) determines the change in LV dimensions after aortic valve replacement, a prospective study is needed that would employ techniques capable of assessing the RGV/EDV

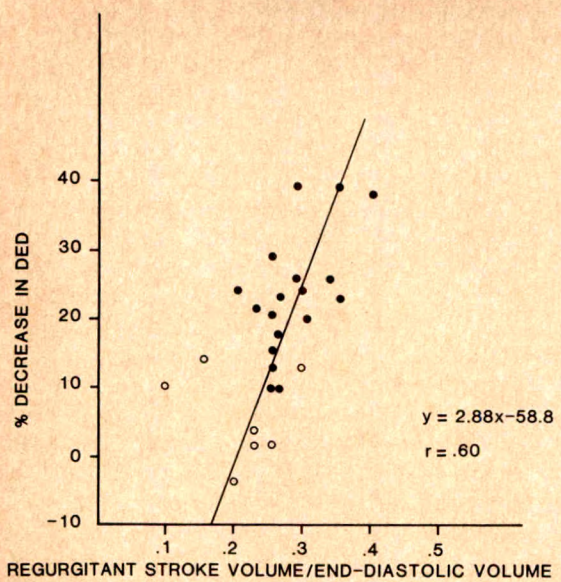

FIGURE 1. Early postoperative (7 to 10 days) percent decrease in left ventricular end-diastolic diameter (DED) as a function of the preoperative regurgitant volume/end-diastolic volume ratio. The **closed symbols** (Group A) represent patients whose end-diastolic diameter fell within the normal range (<3.3 cm/m^2) within 6 to 12 months after aortic valve replacement. The **open symbols** (Group B) represent patients whose end-diastolic diameter remained large (>3.3 cm/m^2) after aortic valve replacement.

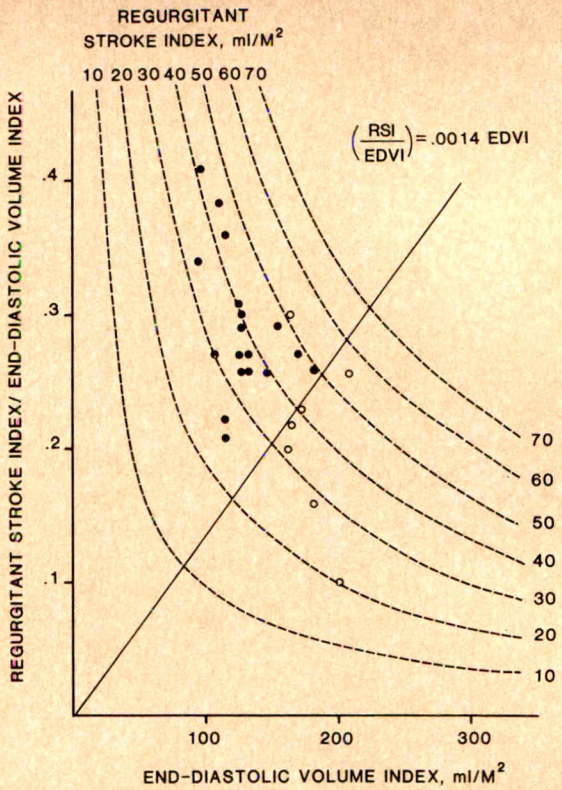

FIGURE 2. Regurgitant stroke index/end-diastolic volume index ratio (RSI/EDVI) as a function of the end-diastolic volume index. The **dashed lines** represent the isopleths of regurgitant stroke index. The **closed symbols** (Group A) and **open symbols** (Group B) are described in the legend of Figure 1. With the exception of 1 patient in Group B, Group A and Group B patients are clearly separated by this analysis.

ratio with confidence. A mechanism for doing so is provided by the fact that the RGV/EDV ratio may be expressed as the product of systolic ejection fraction and regurgitant fraction.* Because both of these latter measurements may be assessed by radionuclide techniques and neither is dependent on absolute volume calibration, an opportunity exists for tracking this index in patients with chronic volume overload using noninvasive techniques.

Pending the results of a prospective study, we sought to test the value of this hypothesis by a retrospective analysis of a group of 25 patients with chronic AR who underwent valve replacement and were reported previously.[4] In this analysis, preoperative echocardiograms were obtained near the time of cardiac catheterization and at 0.3, 3, 6, 9, and 12 months after surgery. LV end-diastolic volume, end-systolic volume and the calculated systolic ejection fraction were derived from the M-mode echocardiogram using the Teichholz volume formula[21] as: ventricular volume = $(7.0/(D + 2.4))D^3$, where D = echocardiographic LV internal dimension. Regurgitant fraction was determined from the LV stroke volume derived from the ventriculogram (30° right anterior oblique projection) and the forward stroke volume calculated using the Fick principle for oxygen. To compare pre- and postoperative LV dimensions, all absolute volume measurements were derived from echocardiographic studies. Although this analysis suffers from the vagaries of nonsimultaneous measurements and the use of different techniques to measure volumes, it is intended only as a means of estimating the utility of the RGV/EDV ratio in predicting the ventricular response to surgery. In Figure 1, the percent decrease in LV diastolic diameter measured within 7 to 10 days after aortic valve replacement is plotted against the ratio of RGV/EDV. The correlation coefficient of this relationship is 0.60.

As mentioned previously, the early postoperative echocardiographic measurements of LV size is remarkably predictive of the patients whose LV chamber will remain reduced in size and be accompanied by regression of hypertrophy. With the exception of 3 patients in Group A, all patients with an early postoperative reduction in end-diastolic diameter of less than 15% were in Group B. In addition, 16 of 18 Group A patients had a preoperative RGV/EDV ratio of greater than 0.25, whereas in 5 of 7 Group B patients the ratio was less than 0.25. Not unexpectedly, the mean EDVI of the Group B patients (180 ± 7 ml/m^2) was significantly greater ($p < 0.0001$) than that of Group A (129 ± 5 ml/m^2); all of the Group B patients had an EDVI >160 ml/m$_2$, whereas in only 2 of 18 in Group A was the EDVI >160 ml/m^2. The regurgitant stroke index, however, did not differ significantly in the 2 groups (39 ± 8 versus 37

* Because regurgitant volume = (regurgitant fraction) (total stroke volume) and total stroke volume = (systolic ejection fraction) (end-diastolic volume) by substitution, RGV/EDV = (systolic ejection fraction) (regurgitant fraction).

± 11 ml/m^2; p = not significant). The reduction in ventricular diameter observed after aortic valve replacement in patients with chronic AR has been reported to be 14 to 24% (average 20%).*[2,4,7,15,18–20,22–24] From the regression equation in Figure 1, this average value would correspond to a RGV/EDV ratio of 0.28.

The same information is presented in a different fashion in Figure 2. Using isopleths of regurgitant stroke index, the relationship between RGV/EDV and EDVI is illustrated to emphasize the hyperbolic relationship between the 2 values. By examining the coordinates of the Group A and Group B patients, one can see that with the exception of 1 Group B patient, a line drawn through the origin with a slope of 0.0014 m^2/ml clearly separates the 2 groups, and does so better than an EDVI of 160 ml/m^2. Thus, this analysis suggests that when the RGV/EDV ratio exceeds 0.0014 EDVI, a good ventricular response to surgery can be expected.

If, indeed, the premise is correct that the regurgitant stroke volume/end-diastolic volume ratio is the major determinant of the *ventricular* response to surgical correction of chronic AR, it follows that the partial functions of end-diastolic volume, regurgitant volume, total stroke volume, systolic ejection fraction, and regurgitant fraction should each be of some predictive value as well. The particular success of end-systolic volume as a means of predicting a good or bad outcome after aortic valve replacement[2–4,7–9] might be explained by the fact that end-systolic volume is directly related to end-diastolic volume and inversely related to total stroke volume, regurgitant volume, and ejection fraction. Thus, a large end-diastolic volume, a small total stroke volume or regurgitant volume, and a reduced ejection fraction would all tend to reduce the RGV/EDV ratio, result in a larger end-systolic volume, and presage a poorer ventricular response to valve replacement. In this regard, it is of interest that Boucher et al[20] found that among 20 patients with chronic AR, "the magnitude of the early postoperative decrease in end-diastolic volume correlated best with the decrease in (total) stroke volume (r = .92)."

If the major portion of the reduction in ventricular size after aortic valve replacement can be demonstrated immediately after surgery,[4,7,15,18–20] there is reason to believe that this volume change is primarily the consequence of elimination of the regurgitant volume and not to an improvement in ventricular function due to relief of the volume overload. Our success in predicting the ventricular response to surgery, therefore, lies in our ability to distinguish the volume overload itself from the chronic malefic effects of this hemodynamic burden on the ventricle.

Therefore, there are convincing conceptual reasons and some experimental data as well to indicate that the relative size of the regurgitant and end-diastolic volumes is the major determinant of the ventricular response to surgical correction of chronic AR. Whatever the explanation for the dilated myopathic ventricle in advanced chronic volume overload, it should be realized that any increase in end-diastolic volume over and above that directly attributed to the regurgitant volume will decrease the proportional volume change after valve replacement and does so in a nonlinear (hyperbolic) fashion.

Appreciation of this fact will not answer the question, "When should we operate on the patient with chronic AR?" However, we should be able to predict, if a patient is to undergo valve replacement, what the ventricular response will be. This information, in turn, will influence our decision regarding surgery. For example, in asymptomatic or minimally symptomatic patients with substantial AR, determination of when the product of systolic ejection fraction and regurgitant fraction begins to decrease may be sufficient reason to recommend valve replacement. The precision with which we can make these judgments will, of course, depend on our ability to assess accurately both systolic ejection fraction and regurgitant fraction in patients with chronic volume overload. The recent success of radionuclide angiography in the quantification of regurgitant fraction[25–29] may provide the necessary tools to test this hypothesis in a prospective study.

* Diameter change derived from echocardiographic measurement or decrease in cube root of angiographic volume.

Current Status of Mitral Commissurotomy: Indications, Techniques, and Results

LAWRENCE I. BONCHEK, MD

Mitral commissurotomy was the first successful cardiac operation in the modern era, beginning with Bailey's report of closed commissurotomy in 1949. As the techniques of cardiopulmonary bypass improved and its risks decreased, the debate between proponents of open versus closed commissurotomy was largely resolved. Open commissurotomy is preferred in most Western countries because it decreases the risk of intraoperative embolism of dislodged thrombotic or calcific material, it allows repair of the subvalvular apparatus, and, as will be discussed further, it permits correction of mitral regurgitation without necessarily replacing the mitral valve. In the United States in particular, closed commissurotomy is rarely taught now, because one cannot entrust to a trainee the responsibility for a blind opening thrust as readily as one can delegate and guide an open commissurotomy. Thus, in the next generation of American surgeons, expertise with closed commissurotomy will be rare or nonexistent.

However, in the underdeveloped and developing countries where resources are limited, rheumatic heart disease is so prevalent, and mitral commissurotomy is performed often, open commissurotomy may be too costly and time-consuming. Similarly, closed commissurotomy is still used extensively in the United Kingdom, where the modern technique of transventricular dilation originated, and there are still many surgeons who are skilled in the technique.

Techniques of Operation

Open mitral commissurotomy is usually carried out through a median sternotomy incision with regular cardiopulmonary bypass techniques that include cannulation of the venae cavae through the right atrium for venous drainage and cannulation of the ascending aorta directly for return of oxygenated blood.[1] The aorta is clamped proximal to the aortic cannula to provide a quiet bloodless field and to prevent release of calcific or thrombotic material into the systemic circulation. Myocardial protection is usually provided by cold cardioplegic arrest. The left atrium is then approached from the right side and is opened posterior to the interatrial septum. Intraatrial clot is evacuated and the lines of commissural fusion are identified. The commissures are divided sharply almost to the anulus. When there is subvalvular fusion of the chordae, these may be incised down to the papillary muscles, and if necessary, the heads of the papillary muscles themselves may be divided to enhance mobility of the leaflets (Fig. 1). Surface calcification of the leaflets may be debrided, provided the underlying valve substance is relatively supple. A few surgeons use more elaborate reconstructive techniques, including correction of anular dilatation or deformity, as discussed herein. Uncorrectable shortening and fusion of the subvalvular apparatus or extensive calcification precludes successful commissurotomy and is an indication for valve replacement. After commissurotomy has been accomplished, the ventricle can be filled with blood or saline solution while the valve is observed directly to assess regurgitation. The left atrial appendage should be oversewn in the course of the operation to eliminate the major source of emboli.

Clearly, these assessments and techniques are not feasible with closed commissurotomy, which is usually carried out through a left thoracotomy. The left atrial appendage is opened through a pursestring suture and any thrombus is evacuated if possible. A dilator is inserted through the apex of the left ventricle, and the valve is opened progressively while its status is monitored by a finger inserted through the left atrial appendage.

Results of Operation

Early mortality: The hospital mortality for open commissurotomy in experienced hands is 1 to 2%. This low risk precludes statistical analysis of factors that increase operative risk, because most reports include between 100 and 200 patients and only 1 to 3 operative deaths. Vega et al[2] reported 2 deaths in 159 patients (1.2%); 1 death was due to "cardiorespiratory failure" and the other to preoperative cerebral embolism. In 1974 Mullin et al[3] reported 100 consecutive operations, with no deaths among 94 patients who had open com-

missurotomy alone or in combination with other valve operations, but 3 deaths from low cardiac output in 6 patients who had commissurotomy with coronary bypass. With current techniques of myocardial preservation, such deaths should be avoidable. Montoya et al[4] reported 2 deaths in 100 consecutive patients, 1 death due to delayed hemorrhage during a hypertensive crisis and 1 to infarction in a patient who underwent concomitant mammary artery implantation. Finally, we[5] reported 100 consecutive operations from the University of Oregon with 1 death due to hemorrhagic pancreatitis. Thus, associated coronary disease was implicated in 4 of the 8 deaths, but coronary disease is an uncommon finding in patients with mitral stenosis, who are usually women under the age of 50 years.

The reported mortality for closed commissurotomy has been somewhat higher, 3.7 to 7%, but the current mortality is probably lower. In a report[6] of 273 patients who underwent operation at the Massachusetts General Hospital between 1963 and 1968, hospital mortality was 3.7%, but there were no operative deaths in 140 consecutive patients operated on after 1970. Fraser et al,[7] in Glasgow, reported a hospital mortality rate of 4.2% in 359 patients operated on from 1957 to 1974, but there was only 1 operative death in the last 77 patients. This lower mortality rate is due not only to improved anesthesia, fluid and blood replacement, drug treatment of arrhythmias, mechanical ventilators, and the like, but also to improved selection of patients for closed commissurotomy. Now that the risks of cardiopulmonary bypass and mitral valve replacement are low, and good prosthetic devices are available, closed commissurotomy is restricted to the most suitable patients. Thus, current improved results with closed commissurotomy reflect experience with a highly selected and very favorable group of patients who would also undoubtedly do extremely well with open commissurotomy.

Long-Term Results

Mortality: Late deaths after isolated mitral commissurotomy are uncommon, as patients in whom recurrent symptoms develop should undergo repeat operation (usually valve replacement; see below), and this should be accomplished with minimal mortality. We[5] reported 1 late death from metastatic breast cancer in 96 operative survivors (3 were lost to follow-up) during a follow-up period that extended to 136 months (mean 46 months). Sixteen patients underwent reoperation with no deaths; 15 had valve replacement and 1 had repeat commissurotomy. In the report of 100 patients by Montoya et al,[4] there was also only 1 late death in an average follow-up period of 51 months. The patient who died had undergone aortocoronary bypass 6 months after commissurotomy, and he died suddenly 3.5 years later, presumably of acute infarction. Mullin et al[3] likewise reported 1 death in 97 survivors of the initial operation. This patient died after tricuspid valve replacement performed 5 months after mitral commissurotomy and tricuspid anuloplasty.

Functional results of operation: Overall, functional results are excellent after open commissurotomy, with 95% of the patients returning to New York Heart Association functional class I or II initially.[5] The late functional results of mitral commissurotomy are affected by 5 major phenomena: (1) left ventricular dysfunction; (2) pulmonary vascular disease, right ventricular failure, or tricuspid regurgitation, or a combination of the 3; (3) systemic emboli; (4) other coexistent cardiac disorders such as coronary artery or aortic valve disease; and (5) residual or progressive mitral valve disease.

Left ventricular dysfunction: In mitral stenosis, unlike other cardiac valve disorders, there is no increase in the pressure or volume load of the left ventricle, and serious left ventricular abnormalities are uncommon.

Nonetheless, Feigenbaum et al[8] documented decreased left ventricular compliance in 19 of 32 patients with pure mitral stenosis. They suggested that obstruction to left ventricular filling might cause "ventricular atrophy," which could explain why improvement in cardiac output often progresses for several months after commissurotomy. However, the apparent decrease in ventricular compliance may have been due to the inevitable shortening of the mitral subvalvular apparatus, which tethers the wall of the ventricle to the valve anulus and restricts diastolic filling of the ventricle. Such studies would have been more persuasive if they had also been performed serially postoperatively in patients with mitral stenosis who underwent mitral valve replacement with excision of the mitral valve and the subvalvular apparatus. In that regard, we have observed decreased compliance of the left ventricle intraoperatively even after valve replacement, and find that at the conclusion of cardiopulmonary bypass left ventricular filling pressure (mean left atrial pressure) can often increase rapidly with transfusion of small increments of blood from the pump-oxygenator. Presumably, this abnormality of compliance is either reversible or hemodynamically unimportant in the long term, because it has not been noted in any large series of patients as a cause of recurrent symptoms after commissurotomy.

On the other hand, substantial depression of left ventricular contractility is found occasionally. Such primary ventricular dysfunction is probably due to previous rheumatic carditis, but might result instead from unrelated cardiomyopathies such as those due to excessive alcohol ingestion or previous viral infection. Because the severity of left ventricular dysfunction in mitral stenosis does not correlate with the duration or severity of the mitral valve disease, early operation cannot be justified to prevent deterioration of left ventricular function. Rather, as will be discussed further, the primary reasons for recommending early commissurotomy are loss of exercise capacity, the high preoperative risk of major systemic emboli, the possibility that the valve will be more pliable if repaired early, and the need to prevent irreversible pulmonary damage.

Pulmonary vascular disease and related abnormalities: The pulmonary hypertension in patients with mitral stenosis has 3 components: (1) the direct hydraulic consequence of obstruction to left atrial emptying, (2) reactive pulmonary vasoconstriction, and (3) interstitial pulmonary fibrosis with mechanical compression of the pulmonary vessels.

Several investigators[9,10] have demonstrated that the decline in pulmonary artery pressure after commissurotomy is due not only to relief of the physical obstruction, which obviously occurs immediately, but also to regression of a vasoconstrictive component of pulmonary vascular resistance. Nonetheless, many patients retain mild-to-moderate pulmonary hypertension despite successful commissurotomy, which suggests that some element of vasoconstriction often persists, or that there is irreversible interstitial fibrosis, or both.

Therefore, it is essential to offer operation before there is irreversible damage to the pulmonary vasculature and right ventricle. The need for concomitant tricuspid valve repair or replacement increases the risk of commissurotomy considerably, but the exact risk is difficult to determine, because combined operations are excluded from most reports of open commissurotomy and, obviously, from all reports of closed commissurotomy. Although tricuspid regurgitation is usually secondary to pulmonary hypertension, tricuspid stenosis can result from rheumatic valvulitis. Reconstructive techniques should be used and valve replacement should be avoided, because mechanical valves in the tricuspid position are prone to thrombosis, and tissue valves have uncertain durability in these patients, who are often young.

Systemic emboli: Prevention of systemic emboli is one of the most important and unequivocal benefits of commissurotomy. In our report of 100 patients,[5] 13 had preoperative emboli and only 2 had postoperative emboli. Furthermore, *sinus rhythm did not provide adequate protection from preoperative emboli*, because 6 of the 67 patients (9%) in sinus rhythm had emboli preoperatively. The risk of emboli was higher in patients with atrial fibrillation, however, and 7 of 32 (21%) had emboli preoperatively. Of the 2 patients with emboli postoperatively, 1 had sinus rhythm and the other had atrial fibrillation. Importantly, we found no correlation between the incidence of embolism and the presence of left atrial thrombus at operation; Mullin et al[3] and Montoya et al[4] found likewise. In contrast, Vega et al[2] found a significant positive correlation in that 27% of their patients with a history of emboli had left atrial thrombi, whereas only 8% of patients without a history of embolism had atrial thrombi. Postoperative emboli were also uncommon in these other reports (Vega, 2%; Montoya, 4%; Mullin, 4%). In our patients, long-term anticoagulation was restricted to older patients with atrial fibrillation, but its use in the other studies was not defined.

Coexistent cardiac disorders: As already noted, coronary artery disease was directly implicated in 4 of the 8 deaths in the reports cited, which dated from the early years of coronary bypass. The number of coronary deaths should be much lower now, because coronary bypass is regularly combined safely with valve procedures that are much more complex than mitral commissurotomy. In general, coexisting disease of the coronary arteries or of other heart valves usually overshadows the need for mitral commissurotomy, and the severity of these other cardiac problems usually determines late survival.

Residual or progressive mitral valve disease: Late deterioration after mitral commissurotomy may be due to *restenosis* of the mitral valve, to residual (unrelieved) mitral stenosis, or to mitral regurgitation induced at operation. The latter is usually apparent immediately, and in the majority of patients with severe iatrogenic regurgitation, the proposed commissurotomy is converted to mitral valve replacement. The incidence of this conversion is infrequently reported and is therefore difficult to assess. We did not assess the issue directly in our report. Montoya et al[4] found replacement necessary in 28% of patients in whom open commissurot-

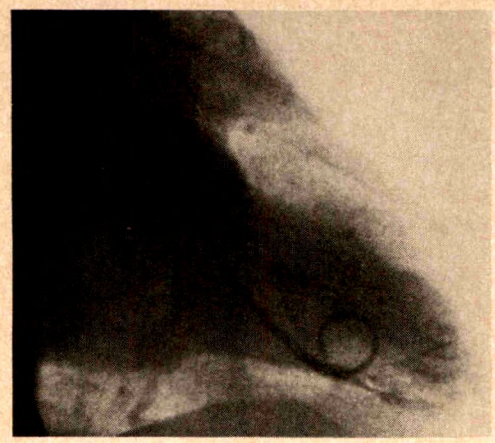

FIGURE 2. Preoperative left ventriculogram in the right anterior oblique projection. Massive mitral regurgitation is apparent.

FIGURE 3. Postoperative left ventriculogram. Mitral regurgitation has been abolished. The Carpentier ring is visible at the mitral anulus, but there is no other prosthetic material and the patient's native valve is intact.

omy had been planned. Grantham et al[6] carried out mitral valve replacement in 20 of 273 patients (8%) undergoing closed commissurotomy.

The need for valve replacement may be decreased considerably by reconstructive techniques to correct mitral regurgitation. Figure 2 displays the preoperative ventriculogram in a patient of mine with severe nonrheumatic mitral regurgitation. A postoperative ventriculogram (Fig. 3) indicates complete correction of the regurgitation without valve replacement. Correction was accomplished using Carpentier's techniques by excision of a portion of 1 leaflet of the mitral valve, shortening of elongated chordae, and correction of anular dilatation by insertion of a cloth-covered, rigid Carpentier ring. Although these techniques are rarely necessary in patients who undergo commissurotomy for pure mitral stenosis, we use them regularly in patients with mitral regurgitation.[11] The techniques of mitral valve reconstruction developed by Carpentier et al[12] can markedly decrease the need for mitral valve replacement in patients with mitral regurgitation.

There is still considerable controversy about the frequency of recurrent stenosis. Only 2 studies provide adequate hemodynamic documentation of restenosis after closed commissurotomy. Such proof requires preoperative hemodynamic assessment of the severity of stenosis, a postoperative study that documents relief of the stenosis, and a later hemodynamic study that demonstrates recurrent stenosis. Higgs et al[13] at the National Institutes of Health found that of 163 patients who underwent mitral commissurotomy and had preoperative and early postoperative catheterization, 45 required late recatheterization for recurrent symptoms. Of these 45 patients, only 5 had recurrent stenosis after initially successful commissurotomy. Sixteen other patients had residual, unrelieved stenosis, 15 had residual stenosis and operatively induced mitral regurgitation, and 99 had other cardiac disorders. Lyons et al[10] reported similar findings on the basis of sequential hemodynamic studies. Thus, restenosis can occur after closed commissurotomy, but it is uncommon in the hands of experienced surgeons. Although the reported incidence of reoperation for restenosis after closed commissurotomy ranges from 3 to 9%, many, if not most, of these operations are undoubtedly necessitated by residual stenosis.

The incidence of restenosis after open commissurotomy is not as easy to assess because the procedure is newer and follow-up is shorter. Reoperation for restenosis was necessary in only 2 of 159 patients followed up by Vega et al[2] (0.4% per patient-year), but the average follow-up was only 3 years. In Montoya's series[4] of 105 patients followed up an average of 51 months, 1 patient had a second open commissurotomy and 2 had valve replacement. Our own study[5] of 100 patients followed up an average of 46 months provided an actuarial analysis of the incidence of late reoperation. Overall, 16 of 99 survivors required reoperation, with an actuarial incidence of 9% at 5 years. The incidence increased thereafter, but the number of patients at risk was too small to permit statistical analysis. We observed a higher incidence of reoperation than Montoya, but the experiences are not comparable. All of their first operations were performed after 1970, when good prosthetic valves were available and were used often. Twenty-eight percent of their patients scheduled for commissurotomy underwent valve replacement. In contrast, our series of patients began in 1960, when prostheses were just being developed. Almost all patients who required reoperation were first operated on before 1970, when prostheses were less desirable than they are now and imperfect native valves were more often preserved. Our study revealed a distinct relation between leaflet deformity and the need for reoperation. Of 77 patients with only fair or poor leaflet anatomy, 17 and 23%, respectively, had undergone reoperation at the time of the study, whereas none of the 10 patients with good leaflet anatomy had done so. Thus, the true incidence of late reoperation after commissurotomy with current techniques and criteria for selection of patients is not clearly defined.

Conclusions

The operative mortality for open commissurotomy alone in experienced hands is ≤1%. Functional results are initially excellent in approximately 95% of patients, and postoperative emboli are rare. Nonsurgical therapy imposes substantial risks of embolism (18% preoperatively in the series of Montoya et al[4] and 13% in our report). Because emboli and left atrial thrombi frequently occur in patients with sinus rhythm, it is difficult to decide which patients should receive chronic anticoagulant therapy preoperatively. Long-term preoperative anticoagulant therapy poses notable risks, with a 5-year mortality that exceeds the combined surgical and late mortality of commissurotomy.

Avoiding all of the risks cited (including tricuspid regurgitation and irreversible pulmonary hypertension) and restoring functional capacity may be well worth the minimal surgical risk to most patients. Open mitral commissurotomy can reasonably be offered to patients with mitral stenosis who wish to function in New York Heart Association class I but are unable to do so. This means that operation should be offered when cardiac symptoms cause curtailment of normal daily activities and should not be withheld until the patient is incapacitated. In addition, a patient who sustains a major systemic embolus should have cardiac catheterization. If hemodynamically significant mitral stenosis is found, the risk of an operation is much less than the risk of another major embolus or chronic systemic anticoagulation. With current diagnostic techniques, including echocardiography, the likelihood of successful commissurotomy can be predicted with reasonable confidence. Obviously, the cardiac surgeon must be experienced in reconstructive mitral surgery, not just in valve replacement. If, in a particular patient, there is uncertainty that the valve will be suitable for commissurotomy, the indications for valve replacement I have discussed elsewhere[14] should be applied, because they are less liberal.

Atrioventricular Nodal Rhythm Reconsidered

WARREN G. GUNTHEROTH, MD, ARTHUR SELZER, MD, and DAVID H. SPODICK, MD

For over 50 years after Tawara's description of the atrioventricular (A-V) node,[1] clinicians and scientists referred to pacemaker activity from that region as A-V nodal or simply nodal. In the mid-1960s, there was a rapid movement toward the use of the term A-V junctional rather than nodal. We believe that the basis for this change was inadequate on both clinical and electrophysiologic grounds, and that the continued use of "junctional" maintains an unnecessary ambiguity. We review here the literature for the original change, and conclude with the grounds for clinical separation of low atrial from A-V nodal pacemakers.

The initial argument against nodal rhythm was based on cellular studies by Hoffman and Cranefield.[2] In 1964, they criticized the use of "so-called nodal beats," because, "In our opinion, there are no automatic fibers in atrioventricular node, although there may be a few at the junction of the lower node with the bundle of His." They particularly objected to the designation "upper nodal rhythms," suggesting that these rhythms actually originate in the atrial tissue of the coronary sinus region.

The first clinical study substituting junctional for nodal rhythm was by Kistin in 1966,[3] without explanation. Scherf made the substitution "official" in an editorial in this journal in 1967,[4] explaining that the uncertainty of automaticity required the change, but only as a temporary expedient pending further studies. Pick and Langendorf in 1968[5] joined in the call for junctional to replace nodal for impulse generation, citing the failure to demonstrate automaticity and added clinical objections. Quoting them directly, "relationships of retrograde P waves to QRS are not only dependent on the proximity of the ectopic pacemaker to atria or ventricles but also on the relative speed of conduction in either direction." The supporting citations were clinical deductions based on surface electrocardiograms. As stated, it is unarguable; that the statement required a change in nomenclature *is* arguable. Pick and Langendorf[5] added a third objection; citing an animal study,[6] "experimentally proved retrograde atrial activation may produce, against the rule, upright P waves in Leads II, III, and aVF." However, this study by Moore et al[6] reported an R-P interval for the retrograde atrial activation of 110 ms, in contrast to a P-R of 100 ms for beats originating in the low right atrium, and a P-R of 110 ms for sinus beats. Pacing the coronary sinus region in human subjects[7] produced inverted P waves in II, III, and aVF, and the P-R interval was only minimally shortened, as Moore had found in the dog.[6]

In 1973, Hecht and Kossman[8] and a group of 8 prestigious cardiologists also recommended replacing "A-V nodal" with "A-V junctional," citing similar reasoning, based on 2 electrophysiologic studies.[9,10] These 2 citations also raised questions about P-wave morphology, but were unambiguous about the sequence of P and QRS in relation to the origin of beats. In the first study in human subjects, junctional beats conducted retrogradely produced diphasic P waves buried in the QRS.[9] Moore et al[10] again reported that atrial beats had P-R intervals, whereas ventricular pacing with retrograde atrial activation produced R-P intervals, without exception.

There is then ample experimental evidence that coronary sinus or low atrial pacemakers have slightly shortened P-R intervals, but retrograde atrial activation produces R-P intervals,[6,10] or at worst simultaneous P and QRS complexes.[9] This is based on a principle that has been repeatedly proved, that the slowest conduction in the entire heart is found in the transitional zone between the atrium and node.[11–13] The most precise correlation between morphology and electrophysiology, using 3-dimensional reconstruction techniques, was reported from Amsterdam in 1974[14]; they found that

TABLE I Values for Atrioventricular Conduction

From His bundle recordings in human subjects,[8] in milliseconds:	
P-R interval = P-H + H-R = 162 ms	
P-H = 119 ms	
H-R = 43 ms	
P-H interval = P-A + A-H = 119 ms	
P-A = 27 ms	
A-H = 92 ms	
From combined morphologic and electrophysiologic[14] study of atrioventricular node, in percent of A-H interval:	
Atrial to atrionodal (AN) region	20%
Activation time for AN region	60%
AN to His bundle	20%
A-H interval	100%

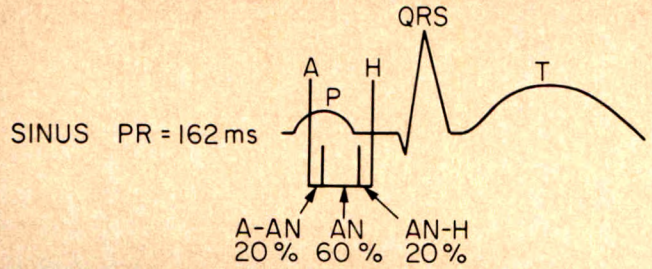

FIGURE 1. A graph indicating temporal relationships of the surface electrocardiogram and His bundle electrogram values,[8] specified in Table I. Below the isoelectric line are percentages of the A-H interval that were found in a combined morphologic and electrophysiologic study.[14] For the drawing, a P-wave duration of 90 ms was assumed, and a QRS duration of 80 ms. The regions of the A-V node (AN, N, and NH) are defined in the text. RA = right atrium.

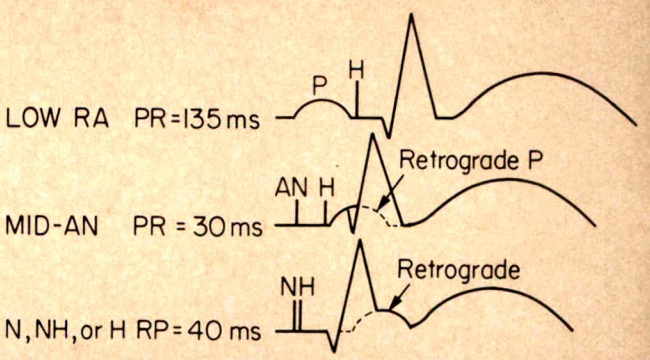

FIGURE 2. Graphic presentation of the P and QRS sequences for ectopic impulse formation. The **top** sequence represents an ectopic impulse beginning in the low right atrium (RA). The **middle** graph represents the sequence for an impulse originating in the mid-point of transitional cells (AN); 30% of the A-H interval would be consumed in anterograde and retrograde conduction, respectively, resulting in a P wave nearly coincident with the QRS and a P-R interval of 30 ms, compared with a sinus beat with a P-R of 162 ms and a low atrial origin with P-R of 135 ms. A beat originating in the N, NH, or H regions would be separated by only a few milliseconds, and all would result in a P wave following the QRS and an R-P interval of 40 ms. (The P wave was deliberately drawn in the upright position, although we believe that the vector will be changed in most cases of ectopic pacemaker, to emphasize the importance of interval and sequence over P morphology).

80% of the atrial-His interval was consumed between the atrial and transitional zone (AN cells) (Fig. 1).

Using the average intervals provided by Hecht and Kossmann[8] from human His bundle recordings, and the subdivisions of the A-H interval observed by Anderson et al,[14] Figure 2 illustrates the P-QRS relationships expected from impulses originating in the low right atrium, midway in the transitional zone (AN), and in the node (N), NH region, or even the His bundle. (The intervals between these last 3 are so short that they are lumped.) The results are in keeping with the observed P-R and R-P intervals reported earlier.[6,7,9,10]

In rereading the original criticisms on A-V nodal terminology,[2,5,8] they shared a substantive objection to the subdivision of nodal into upper, middle, and lower A-V node on the basis of surface electrocardiograms. On the basis of cellular studies from many centers, we agree that it would be impractical, if not impossible, to identify the site of origin within the node by clinical means. This does not invalidate the original term A-V nodal, nor does it invalidate the clinical separation of nodal from atrial pacemaker activity. There is, in fact, nearly unanimous agreement[11–14] that the great majority of conduction delay between atrium and ventricle or between ventricle and atrium occurs in the transitional zone (AN cells) between the 2, permitting easy separation of low atrial pacemakers from nodal on the simple basis of initial occurrence of a P or a QRS complex. The term junctional unnecessarily obscures that important clinical distinction.

To return to the first objection to nodal rhythm, automaticity,[2] Watanabe and Dreifus[15] in 1968 reported that the great majority of spontaneous A-V junctional rhythms arose from the NH region. And finally, Wit and Cranefield[16] provided a welcome release from 15 years of uncertainty; they found automaticity in mid-nodal (N) cells by experimentally uncoupling the A-V node from the atrium.

In summary, the term junctional makes no improvement in the understanding of the origin of ectopic rhythms over the earlier, historic term, A-V nodal. Because A-V junctional is now used to include low atrial pacemakers that can be separated clinically by the presence of a measurable P-R, that term is more ambiguous than the current state of our knowledge requires. We urge the abandonment of that term, and the restoration of A-V nodal, without clinical subdivision, as the preferred term for automatic rhythms from the A-V node.

Hemodynamics of Mitral Regurgitation (Julio C. Davila)

This report, part of the symposium on mitral regurgitation (MR), describes hemodynamic features of MR and physiologic sequelae of surgical reduction of mitral anular size. Of 128 patients with significant MR, with or without mitral stenosis, all had right-sided cardiac catheterization, and 22 had left atrial puncture. Of 58 patients operated on, 56 had hemodynamic studies performed at surgery, before and after either partial or complete elimination of MR. The left-sided pressure changes of MR were documented at operation before and after mitral valve manipulation. The hemodynamic derangements usually reverted to normal. The left ventricular (LV) end-diastolic pressure and total LV volume, however, sometimes failed to revert to normal, and often these patients died despite apparent diminution or elimination of MR by operation. The author emphasized that patients with long-standing severe MR may not be benefited by the operation because when LV dilatation, the major compensation of MR, is severe, correction of MR actually may aggravate myocardial dysfunction by abolishing the "escape exit" into the low pressure left atrium and thus may increase LV work. He concluded that operative candidates should be selected before irreversible damage to LV myocardium had occurred. This report introduced important concepts of surgical treatment of MR, and is a fine example of physiologic orientation of early surgeons of valvular heart disease.

Modern Concepts of Hypertension and Its Treatment (Joseph H. Hafkenschiel, Edward Weiss, William Likoff, John K. Clark, and Charles C. Wolferth)

This 19-page article reports a conference on systemic hypertension (SH) at Lankenau Hospital, Philadelphia. SH was considered to have 3 major causes: hereditary, renal, and psychogenic. This latter concept was given considerable emphasis, and the "personality inside an individual" was considered etiologically important in most patients. A study of 130 patients with SH who were followed up for >5 years was reported: Only 66% survived for 5 years. Adrenalectomy for refractory SH was still considered acceptable therapy, but the conference invoked considerable dispute regarding the necessity, if any, for medical treatment for less severe forms of SH. Weiss stated, "In the so-called malignant SH, it has been demonstrated that ganglionic blockers prolong the life of these patients. Beyond that I have not seen any adequate demonstration that the drug treatment of SH prolongs life or changes the course of the vascular disease." Medical therapy consisted essentially of rauwolfia and hydralazine. The results of chlorothiazide, then a new drug, were considered impressive. Some clinicians, however, remained convinced that drug therapy was used too early and objected to the use of potent drugs in the treatment of early or mild SH.

This conference reflects the paucity of scientific data then available on SH. No definition of SH was given. In the last 25 years, the importance of treating SH has become obvious, and treatment has become more vigorous and introduced at earlier stages. However, recent observations on *mild* SH treated with thiazide diuretic drugs suggest a reconsideration of this approach.

Ebstein's Anomaly (Joseph B. Vacca, Donald W. Bussman, and J. Gerard Mudd)

This report describes 3 cases of Ebstein's anomaly, and reviews the data on 105 cases previously reported on since Ebstein's original description in 1866: 55 were diagnosed clinically and 53 at necropsy. The typical clinical, radiographic, and electrocardiographic findings were described, and the frequent association of atrial septal defect and rhythm abnormalities was noted. Cardiac catheterization was considered helpful and diagnostic, but was acknowledged to be hazardous and possibly dangerous in patients with this anomaly. Diagnosis of Ebstein's anomaly now is obviously much easier because of echocardiography with or without use of the intracavitary electrode. Despite the improved diagnostic accuracy and more successful treatment of rhythm abnormalities, however, surgical treatment remains less than ideal, and the overall survival has probably improved only slightly in the last 25 years.

Pulmonary Atresia With Ventricular Septal Defect and Aortic Regurgitation: Diagnosis by Echocardiography With Diastolic Vibration of Both Right and Left Sides of the Ventricular Septum

NICHOLAS DePACE, MD
MORRIS N. KOTLER, MD
GARY S. MINTZ, MD
CHARLES E. BEMIS, MD
E. ELAINE GLAZIER-LASKEY

High-frequency[1] diastolic fluttering of the left side of the ventricular septum has been reported with aortic regurgitation (AR)[1] and of the right side of the ventricular septum with a ruptured aneurysm of the sinus of Valsalva.[2] This report describes the echocardiographic features of a patient with pulmonary atresia and ventricular septal defect (VSD) with AR.

A 26-year-old man with cyanotic congenital heart disease was admitted for precise diagnosis. Blood pressure was 120/60 mm Hg. The peripheral pulses were collapsing. Auscultation revealed a single accentuated second sound, a grade 3/6 decrescendo blowing diastolic murmur along the left sternal border, and a presystolic murmur and short, early grade 2/6 ejection murmur at the apex. The electrocardiogram demonstrated right atrial and biventricular enlargement. Chest X-ray revealed right ventricular enlargement and a right aortic arch with an absent pulmonary trunk and evidence of bronchial collateral circulation. M-mode and 2-dimensional echocardiography demonstrated aortic overriding of the ventricular septum, a large VSD, and marked right ventricular hypertrophy, and these findings were confirmed by catheterization. The left ventricle was enlarged and the pulmonary valve was not visualized. The aortic valve cusps were thickened. On M-mode echocardiography, diastolic high-frequency fluttering of the mitral valve as well as both sides of the ventricular septum was recorded (Fig. 1). At catheterization the pulmonary arteries were opacified by bronchial collateral vessels when contrast material was injected into the descending aorta. Significant (3+ to 4+) AR was noted.

The role of echocardiography in the diagnosis of conotruncal abnormalities is well defined.[3,4] Incompetence of the systemic arterial trunk in these disorders is present in approximately 20% of patients.[4] However, the characteristic regurgitant murmur may be absent in 25% of these patients.[5] The finding of diastolic fluttering of the mitral valve and fluttering of both sides of the ventricular septum in the present case suggested incompetence of the systemic arterial trunk. The diastolic vibrations are presumably due to the effect of the valvular regurgitant jet striking the septum. In 62 patients with aortic overriding, Assad Morrell et al[3] noted fluttering of the mitral and tricuspid valves in 7 and 5 cases,

From the Likoff Cardiovascular Institute, Hahnemann Hospital and University, 230 North Broad Street, Philadelphia, Pennsylvania. Manuscript received April 13, 1983; revised manuscript received May 2, 1983, accepted May 5, 1983.

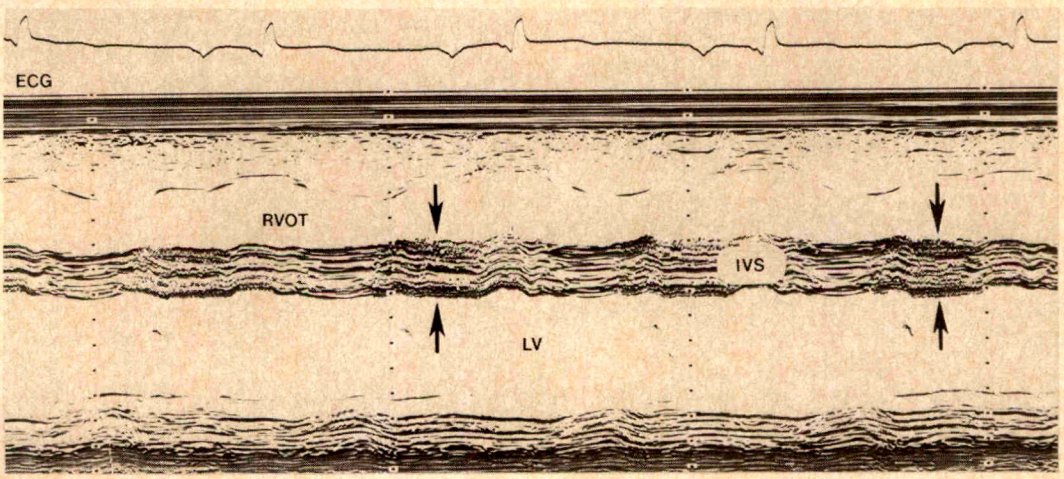

FIGURE 1. M-mode echocardiogram of the left ventricle (LV) below the level of the mitral valve. Fluttering of both sides of the interventricular septum (IVS) is noted (**arrows**). The right ventricular wall measures 13 mm in thickness. RVOT = right ventricular outflow tract.

respectively, in patients with truncal incompetence. If fluttering of both atrioventricular valves or both sides of the ventricular septum is recorded, aortic override should be suspected even though it may not be demonstrated by M-mode echocardiography.

Real-Time 2-Dimensional Echocardiographic Imaging of Right-Sided Cardiac Vegetations in Ventricular Septal Defect

NEARCHOS E. AGATHANGELOU, MD
LUIS A. DOS SANTOS, LMC
BASIL S. LEWIS, MD

Echocardiography is a valuable bedside technique for detecting cardiac vegetations in patients with infective endocarditis.[1] However, most reports concern left-sided cardiac structures, and few reports describe vegetations on the tricuspid or pulmonic valves[2–5] or in the right ventricle.[6,7] This report presents 2-dimensional (2-D) echocardiographic findings in 2 patients with ventricular septal defect (VSD) complicated by ventricular endocardial or pulmonic valvular alpha Streptococcus endocarditis with severe congestive heart failure.

From the Cardiovascular Research Unit, Department of Cardiology, Baragwanath Hospital and the University of the Witwatersrand, Johannesburg, South Africa.

This study was supported in part by a grant from the Stella and Paul Loewenstein Cardiac Fund of the University of the Witwatersrand, Johannesburg, South Africa. Manuscript received July 1, 1982; revised manuscript received April 8, 1983, accepted April 12, 1983.

Patient 1 (24-year-old man): *The 2-D echocardiogram showed a defect high in the ventricular septum (Fig. 1). Attached to the right side of the septum around and above the defect were large mobile vegetations (15 × 25 mm). The vegetations projected into the right ventricular outflow tract during systole (Fig. 1, left) and closed the VSD during diastole (Fig. 1, right). Movement of the vegetations in systole and diastole was probably related to the left-to-right shunt. The left ventricle and left atrium were not enlarged and the left ventricle contracted well. There was no apparent attachment of the vegetations to the tricuspid or pulmonic valves, which were normal in structure and function. After 6 weeks of appropriate medical treatment, the diagnosis was confirmed by cardiac catheterization and operation, at which a 1 cm VSD was closed in the infundibular septum 2 cm below the pulmonic valve. At operation, there were no large vegetations, but some fibrosed thickening on the rim of the defect. The absence of vegetations at surgery may be the result of successful antibiotic treatment, but part of the vegetations embolized to the lungs during the period of medical treatment. The postoperative course was uneventful.*

Patient 2 (11-year-old girl): *Two-dimensional echocardiography showed a large high VSD in the region of the membranous septum (Fig. 2). Large vegetations were seen on the pulmonic valve, and pulmonic cuspal tissue fluttered chaotically in the right ventricular outflow tract and pulmonary trunk, indicating a torn pulmonic cusp. The patient received 6 weeks of medical therapy and had marked clinical improvement.*

In both patients, 2-D echocardiography confirmed the clinical diagnosis of VSD and infective endocarditis, with accurate delineation of the size and site of the large right-sided cardiac vegetations. The high quality of the pictures was partly related to the newer image-processing techniques, but also to the physique of the pa-

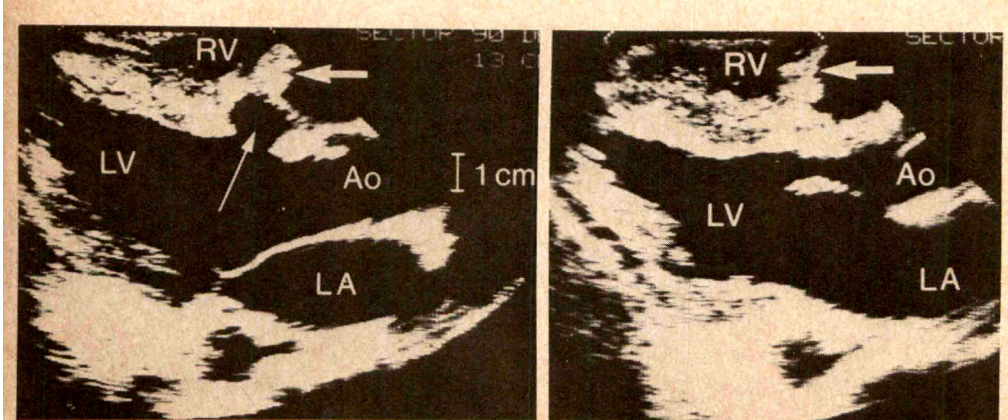

FIGURE 1. Left, echocardiogram (parasternal long-axis view, systolic frame), showing the defect in the interventricular septum (**fine arrow**) and large pedunculated vegetations (**heavy arrow**) in the right ventricular (RV) outflow tract. **Right,** diastolic frame. The defect has been closed by part of the vegetations (**heavy arrow**). Ao = aortic root; LA = left atrium; LV = left ventricle.

tients, to careful attention to echo-recording technique and to the use of appropriate echocardiographic views to demonstrate the right-sided cardiac chambers and valves. The subcostal and apical views were particularly useful in visualizing the tricuspid and pulmonic valves, the right ventricle, and its inflow and outflow tracts.

The clinical implication of large vegetations on left-sided cardiac structures has been recognized: (1) Valve destruction is usually severe, so that there is a high likelihood of the need for early or urgent operation, whereas (2) major systemic emboli occur in ≤30% of patients.[1] These 2 patients behaved in a similar manner, with severe destruction of the pulmonic valve in 1 and recurrent pulmonary emboli in the other. The hemodynamic lesions, however, were tolerated well and emboli, although important, were less crucial.

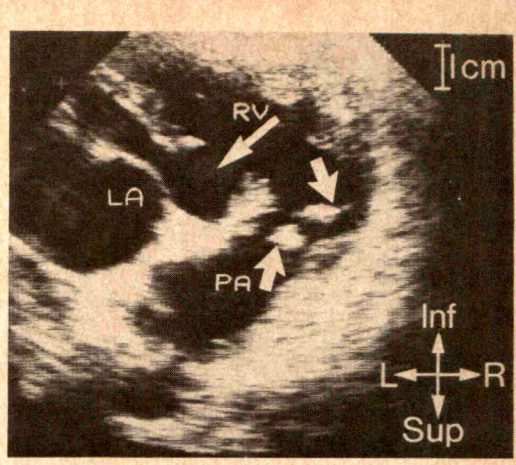

FIGURE 2. Echocardiogram (subcostal view) in the long axis of the right ventricular outflow tract, showing the ventricular septal defect (**long arrow**) in the high interventricular septum and large vegetations (**heavy short arrows**) on the pulmonic valve. LA = left atrium; PA = pulmonary artery; RV = right ventricle.

Idiopathic Restrictive Cardiomyopathy: Differences of Left Ventricular Relaxation and Diastolic Wave Forms from Constrictive Pericarditis

YUZO HIROTA, MD
TOSHIAKI KOHRIYAMA, MD
TETSUYA HAYASHI, MD
KIYOTAKA KAKU, MD
HIKARU NISHIMURA, MD
TAKAHARU SAITO, MD
YASUSHI NAKAYAMA, MD
MICHIHIRO SUWA, MD
MASAYA KINO, MD
KEISHIRO KAWAMURA, MD

It has been frequently emphasized that the clinical features and hemodynamic characteristics of restrictive cardiomyopathy are similar to those of constrictive pericarditis.[1–3] Early diastolic dip and subsequent plateau pattern of the diastolic ventricular pressure curve (square root sign) have been considered to be characteristic in these diseases.[1,3] Left ventricular (LV) pressure was recorded with a tip manometer system in 3 patients with restrictive cardiomyopathy and constrictive pericarditis. This report describes the differences of LV relaxation and diastolic wave forms of these 2 diseases.

Among 263 patients who underwent diagnostic cardiac catheterization between January 1980 and December 1981, 3 had idiopathic restrictive cardiomyopathy and constrictive pericarditis. The diagnostic criteria of idiopathic restrictive

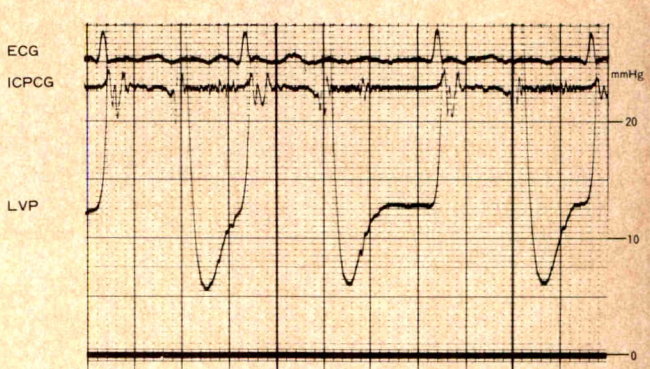

FIGURE 1. A high-gain left ventricular pressure (LVP) of constrictive pericarditis (Patient 2). The pressure was recorded with a Mikro-tip® angiocatheter with the simultaneous recordings of intracardiac phonocardiogram (ICPCG) and electrocardiogram (ECG). A typical square root sign was present.

From the Third Division, Department of Internal Medicine, Osaka Medical College, Takatsuki City, Osaka, Japan.

This study was supported in part by a grant from the Ministry of Health and Welfare of the Japanese Government for the survey of idiopathic cardiomyopathies in Japan. Manuscript received September 2, 1982; revised manuscript received March 28, 1983, accepted April 1, 1983.

TABLE I **Left Ventricular Volume and Indexes of Contractility and Relaxation in Patients with Restrictive Cardiomyopath and Constrictive Pericarditis**

Patient	EDVI (ml/m^2)	EF (%)	peak (+)dP/dt (mm Hg/s)	peak (−)dP/dt (mm Hg/s)	peak (+)dp/dt / peak (−)dP/dt	(r
Restrictive Cardiomyopathy						
1	69	53	1,434	969	1.48	
2	73	63	1,480	680	2.18	1
3	82	76	1,410	590	2.39	1
Constrictive Pericarditis						
1	59	66	1,065	1,410	0.76	
2	54	61	1,500	2,062	0.73	
3	54	49	1,328	1,426	0.93	
Normal value (n = 22, M ± SD)	69 ±20	65 ±7	1,681 ±413	1,923 ±440	0.90 ±0.15	

Normal values are based on 22 patients without significant heart disease.[4,5]
EDVI = end-diastolic volume index; EF = ejection fraction; M = mean; peak (+) and (−)dP/dt = peak rate of left ventricular pressure inc and decrease; SD = standard deviation; T = the time constant of left ventricular pressure decrease.

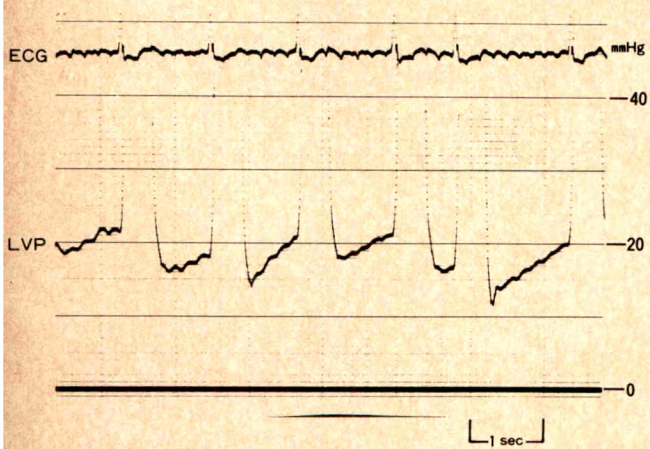

FIGURE 2. A high-gain left ventricular pressure (LVP) tracing of restrictive cardiomyopathy (Patient 3). Early diastolic dip and square root sign were absent even with the elevation of diastolic pressure and slow heart rate.

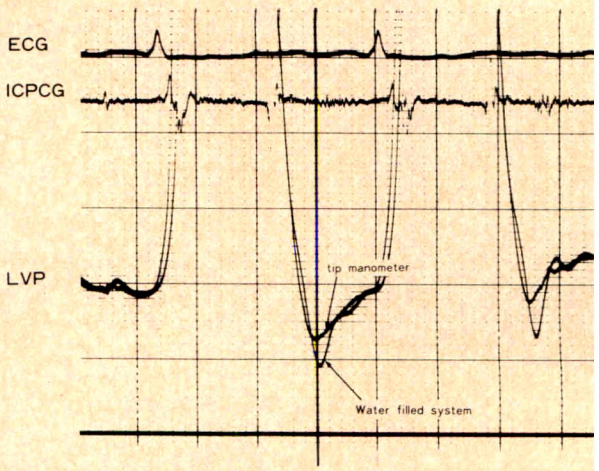

FIGURE 3. Simultaneous left ventricular pressure (LVP) recordings a tip manometer system and a fluid-filled system in restrictive ca myopathy (Patient 1). Early diastolic dip and square root sign were only in the tracing obtained with a fluid (water)-filled system. phenomenon was probably due to the exaggeration of the wave by the artifact of a fluid-filled system.

cardiomyopathy were (1) normal LV volume and ejection fraction, (2) evidence of stiff ventricle, (3) absence of severe LV hypertrophy, (4) absence of hypertrophic cardiomyopathy, (5) histologic findings consistent with stiff ventricle, and (6) unidentifiable cause of heart disease.

Precise descriptions of the catheterization procedures and data processing have been published elsewhere.[4,5] *Right ventricular (RV) pressure was recorded with a fluid-filled system, and LV pressure was recorded with a tip manometer system (Millar Instruments). RV or LV endomyocardial biopsy or both was performed in all cases of restrictive cardiomyopathy. One patient with restrictive cardiomyopathy and 3 patients with constrictive pericarditis underwent pericardiectomy.*

Both RV and LV end-diastolic pressures were elevated in both of the diseases (restrictive cardiomyopathy: RV: 13, 6, 14 mm Hg, LV: 21, 12, 19 mm Hg; constrictive pericarditis: RV: 12, 13, 16 mm Hg, LV: 16, 13, 18 mm Hg), and LV end-diastolic pressure was higher than that of the right ventricle in restrictive cardiomyopathy. Whereas high-gain LV pressure sho square root sign in all cases of constrictive pericar (Fig. 1), this sign was not seen in any of the restric cardiomyopathies (Fig. 2). In the pressure tracing corded simultaneously with a fluid-filled system a tip manometer system, square root sign was seen in the tracing with a fluid-filled system in restric cardiomyopathy (Fig. 3). Hemodynamic parameter these 6 patients are summarized in Table I with normal values of our laboratory.[4,5] Whereas the derivative curve of LV pressure in constrictive p carditis showed some characteristics of that of nor left ventricle, that is, the negative deflection of the derivative curve was much larger than the positive flection,[4] the negative deflection was much smaller t the positive in restrictive cardiomyopathy. The ind of LV relaxation were in the normal range in constric

pericarditis, and relaxation was markedly prolonged in restrictive cardiomyopathy.

Restrictive cardiomyopathy is frequently associated with systemic infiltrative diseases, and the idiopathic form is very rare. The possibility of secondary cardiomyopathy was ruled out in all 3 cases with the histologic examination of the biopsy specimens, which showed thickening of the endocardium and moderate myocardial fibrosis without any infiltrative substance.

The similarity of this disease to constrictive pericarditis has been emphasized because of elevated ventricular filling pressures, normal systolic function, and square root sign of the diastolic pressure curve. Although Meaney,[1] Benotti,[3] and their co-workers included this sign in their diagnostic criteria of restrictive cardiomyopathy, Chew et al[6] did not find this sign in their 3 patients with cardiac amyloidosis whose LV pressures were recorded with a tip manometer system. For the production of square root sign, an accelerated filling rate during early diastole and a later plateau are necessary. LV filling rate was reported to be accelerated with a later plateau,[1,2] or uniformly depressed during whole diastole[2,6,7] in cardiac amyloidosis. This difference has been postulated as being the result of uneven distribution of amyloid in the myocardium in some cases.[2,7] Although Tyberg et al[7] found square root sign in their patients with cardiac amyloidosis with a uniformly depressed diastolic filling, they suspected this was due to the artifact of fluid-filled system. This phenomenon, "pseudo-square root sign," was demonstrated by the simultaneous recordings of the pressure with a fluid-filled system and a tip manometer system (Fig. 3).

Normal relaxation, normal compliance during early diastole, and sudden elevation of stiffness of the ventricle are necessary for the production of an accelerated early diastolic filling with a later plateau, and therefore the production of square root sign. In constrictive pericarditis, LV relaxation was normal, and LV compliance must be normal until the ventricle is constricted with the stiff pericardium. Therefore, square root sign is expected in this disease from these pathophysiologic points. On the other hand, restrictive cardiomyopathy is characterized by stiff ventricle by definition, and LV relaxation was markedly prolonged. We wonder how such a stiff ventricle could dilate quickly only during early diastole. Although our experience is limited to only 3 patients, abnormal relaxation, stiff ventricle, and hence absence of square root sign seem to be prerequisite factors for restrictive cardiomyopathy.

Myocardial Infarction Complicated by Rupture of Both Ventricular Septum and Right Ventricular Papillary Muscle

ELLIS LADER, MD*
STEPHEN COLVIN, MD†
PAUL TUNICK, MD*

Rupture of a right ventricular (RV) papillary muscle is an extremely rare event during acute myocardial infarction (MI).[1] This report describes a patient with this complication.

A 74-year-old man with no history of heart disease was admitted after several days of intermittent chest discomfort and after an electrocardiogram showed new Q waves in leads III and aVF. Initial examination revealed a normal blood pressure, clear lungs, no jugular venous distention, and a previously noted grade 2/6 systolic ejection murmur along the left sternal border. Two days later, the patient had prolonged chest pain, accompanied by S-T segment elevations in leads II, III and aVF. Examination now disclosed pulmonary rales, jugular venous distension to the angles of the jaw with the patient sitting upright, and a new grade 3/6 coarse holosystolic murmur heard at the apex and the lower left sternal border. Catheterization (Swan-Ganz) revealed a left-to-right intracardiac shunt at the RV level (Table I).

The patient's condition gradually deteriorated over the next 10 days. At cardiac catheterization, the right coronary artery was totally obstructed (midportion) without significant stenosis in any major left coronary artery. Left ventricular cineangiography demonstrated a ventricular septal defect with a large shunt into a dilated right ventricle. The markedly elevated right atrial pressures with large v waves suggested tricuspid regurgitation (TR) (Table I). At surgery, the ventricular septal defect was repaired with a Dacron® patch. The posterior papillary muscle of the tricuspid valve was seen to have a necrotic tip which had ruptured completely; the valve was replaced with a procine bioprosthesis. The patient was discharged 1 month later and has been followed up for 18 months with no chest pain or limitation of activity.

TABLE I Catheterization Data

Site	Day 4 Pressure (mm Hg)	Day 4 O_2 Sat (%)	Day 14 Pressure (mm Hg)	Day 14 O_2 Sat (%)
Inferior vena cava	. . .	. . .	. . .	59
Superior vena cava	. . .	. . .	. . .	38
Mean right atrial pressure	5	66	16	57
a wave	. . .	. . .	22	. . .
v wave	. . .	. . .	26	. . .
Right ventricle	48/5	82	53/20	78
Pulmonary artery	44/12	90	57/18	75
Mean pulmonary capillary wedge pressure	10	. . .	20	. . .
Ascending aorta	. . .	98	88/52	87
Left ventricle	. . .	. . .	88/22	. . .

O_2 Sat = oxygen saturation.

TR is an uncommon complication of MI.[1–6] The most likely cause of TR in this setting would be MI involving a tricuspid valve papillary muscle, with associated akinesia or dyskinesia of adjacent RV wall. This mechanism is analogous to that postulated to produce mitral regurgitation during MI. One would therefore expect TR in these circumstances to be associated with a posterior wall left ventricular MI with accompanying RV infarction.

A review of previous reports disclosed 7 cases of TR complicating MI. All occurred after an inferior wall MI. Tricuspid valve papillary muscle infarction with rupture was found at autopsy in 1 case,[1] and infarction without rupture was noted at autopsy in another.[2] Tric valve papillary muscle infarction without ruptur seen at the time of surgical replacement of the tric valve in 1 patient.[3] In a fourth case, the tricuspid was replaced, but the morphologic findings wer reported.[4] TR was diagnosed in 3 other patients years after an inferior wall MI; the diagnosis was clinically in 1 patient[5] and confirmed with right-cardiac catheterization in 2 others.[5,6]

The patient described in this report had a lar involving the walls of both ventricles, complicat a ruptured tricuspid valve papillary muscle and tured ventricular septum. The TR was exacerbat the RV MI, and was made even worse by the seco pulmonary hypertension and the large left-to shunt across the ventricular septal defect. Th volume overload and elevated pressure probably tributed to the rupture of the infarcted tricuspi pillary muscle; the low-pressure RV characteristic account for the extreme rarity of such an event.

Demonstration of Prostaglandin E_2 and $F_{2\alpha}$ in Atrial Tissue of Patients With Heart Disease

EDGARDO ESCOBAR, MD
BERTA ZAMORANO
RAUL GAZMURI, MD

Prostaglandin (PG) synthesis has been demonstrated in a variety of cardiac tissue preparations from experimental animals.[1–4] Although PG has been reported in blood samples of the coronary sinus in human beings,[5] no data on PG concentration in human cardiac tissue have been reported. This investigation sought to identify PG and to estimate the amount present in the atria of patients with heart disease.

PGE_2 and $PGF_{2\alpha}$ were determined in atrial tissue of 6 patients (2 men and 4 women) at the time of cardiac surgery.

From the Department of Medicine, Faculty of Medicine, Hospital Salvador, and Department of Ecological Sciences, Faculty of Basic Sciences, University of Chile, Santiago, Chile.

This work was supported by Grant M-1156-18333, Department for Research Development, University of Chile, Santiago, Chile. Manuscript received April 6, 1983, accepted May 2, 1983.

The diagnosis was mitral stenosis in 4 patients, atrial s defect in 1, and aortic regurgitation in 1. All patients in New York Heart Association functional class II o Their ages ranged from 23 to 52 years. The samples obtained at surgery, briefly washed in cold Krebs solu and weighed. The tissues were stored at −20°C for s quent homogenization with a mortar and pestle in aqueous ethanol and sand; the homogenate was stirre 2 hours at room temperature (4 ml/g of tissue). The mi was centrifuged at 1,000 rpm and the supernatant acidified to pH 3 with formic acid (98%). After extra of acidic lipids from the supernatant and separation by acid chromatography (100 mesh, Mallinckrodt), we d mined PGE_2 and $PGF_{2\alpha}$ concentration by radioimmuno using Dray's method.[6]

TABLE I Prostaglandin (PG) Concentration in Atrial Tissue of Patients With Heart Disease (ng/mg Protein)

Diagnosis		Right Atrium PGE_2	Right Atrium $PGF_{2\alpha}$	Left Atrium PGE_2	Left Atrium PGF
MS	M	52	25	107	91
MS	F	50	26	110	95
MS	F	52	27	116	92
MS	F	. . .	. . .	163	90
ASD	F	20	11	. . .	. . .
AR	M	19	14	24	13

AR = aortic regurgitation; ASD = atrial septal defect; MS = n stenosis.

Unlabelled PG was obtained from Upjohn, tritiated tracer from New England Nuclear, and the appropriate antiserum from the Pasteur Institute. The overall recovery after purification (extraction and chromatography) was between 75 and 85%. Protein was measured by the method of Lowry et al.[7]

We demonstrated that PG is present in human atrial tissue. It is possible that PG might participate in the cardiac response to certain forms of heart disease (Table I). No inference can be made about the concentration of PG in the normal human heart under physiologic conditions.

Selective Coronary Angiography by Translumbar Aortic Puncture

P. H. NATH, MD
BENIGNO SOTO, MD
JOHN H. HOLT, MD
LOWELL F. SATLER, MD

Multivessel coronary artery disease is frequently present in patients when aortoiliac and cerebrovascular occlusive disease coexist. In this group of patients surgical relief of carotid and iliofemoral arterial stenosis without myocardial revascularization carries a significant risk of perioperative myocardial infarction.[1] In some patients, arterial access for angiography is impossible because all peripheral pulses are absent. Whereas intravenous digital subtraction angiography[2] can provide adequate visualization of the aortic arch and extracranial cerebral vasculature, there is no substitute for selective coronary angiography. A patient is described in whom selective bilateral coronary angiography was performed by way of the translumbar aortic approach.

A 49-year-old man with aortoiliac and bilateral carotid arterial stenosis underwent unsuccessful attempts at arterial catheterization from both femoral and left axillary arteries. An intravenous digital subtraction angiogram demonstrated occlusion of the innominate and left subclavian arteries and subtotal obstruction of the left common carotid artery. In view of the widespread atherosclerosis, significant multivessel coronary arterial disease was suspected and selective coronary angiography through the translumbar route was performed. We believed that selective coronary catheterization was best performed by preshaped catheters, which are most safely introduced through an introducer sheath. A 30-cm-long introducer sheath was prepared from 0.131-inch (outer diameter) clear Teflon® angiographic tubing (Angiograf, Inc.), which accepted a 7F Judkins catheter. The tip was tapered to 0.118 inch. The proximal end of the sheath was fitted with a hemostat valve over a Luer-Lock adapter. Another 45-cm-long 7F Teflon angiographic tubing was tapered over a 0.038-inch spring guide to act as a dilator (Fig. 1). With the patient in the prone position a standard "upstream" translumbar puncture was made below the twelfth rib 6 to 8 cm lateral to the midline with an 18.0 gauge translumbar needle with a Teflon sheath in a steep oblique fashion. Once the aortic lumen was entered, a 0.038 inch J-tip guide wire was introduced and the sheath was deflected into the thoracic aorta. The 18.0 gauge sheath was removed and the soft tissue tract was dilated with use of nephrostomy dilators, taking care not to puncture the aorta. Then the 45-cm-long 7F dilator was fitted in a coaxial fashion into the introducer sheath and the whole system was introduced into the aorta, without any difficulty over the guide wire. The guide wire and the dilator were removed and selective catheterization of both coronary arteries was performed using the Judkins technique without difficulty (Fig. 2). After the procedure, computed tomographic images of the retroperitoneum were obtained. A small amount of periaortic hemorrhage was seen as slight thickening of the left crux of the diaphragm (Fig. 3). The patient's hematocrit was unchanged during the next 2 days. The patient subsequently had saphenous venous grafts to the left anterior descending and right coronary arteries.

Catheter translumbar aortography, introduced by Amplatz[3] in 1963, significantly decreased the complications of the needle translumbar technique. Stocks et al[4] described a modification of Amplatz's technique in

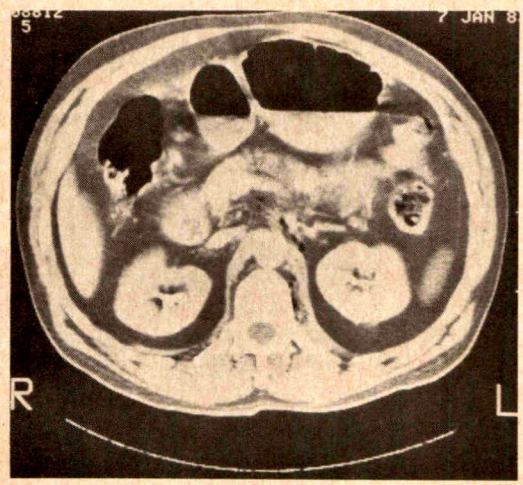

FIGURE 3. Computed tomographic scan of the abdomen 1 cm below the level of the aortic puncture site. Note the thickening of the left crux of the diaphragm caused by small amounts of periaortic hemorrhage.

1969, wherein they substituted a 60-cm-long needle and Teflon sleeve so that aortic arch and selective cerebral angiography could be performed. Recently, Maxwell et al[5] described a patient similar to ours in whom they performed selective catheterization of a dominant left coronary artery by substituting a preshaped catheter for the Teflon sleeve described by Stocks et al.[4] We, too, believed that exchange of a preshaped catheter would not be feasible using their technique. It would not have been possible to obtain enough torque control to perform catheterization using Sones' technique. Hence, we used an introducer sheath. We were apprehensive about the diameter of the sheath and were pleasantly surprised to note the inconsequential amount of periaortic hemorrhage in the computed tomographic scan performed after the procedure. However, with this technique there is a greater risk of significant retroperitoneal hemorrhage than with standard translumbar aortography. Hence, we believe that this technique is a safe and worthwhile alternative to coronary angiography in patients in whom there is no other access to the vascular system.

Idiopathic Severe Bilateral Atrial Dilation

SHMUEL RATH, MD
ADAM SCHNEEWIESS, MD
ALEXANDER BATTLER, MD
YEDAEL HAR-ZAHAV, MD
HENRY N. NEUFELD, MD

Idiopathic dilation of the right atrium is a rare anomaly, with 30 cases having been described. The etiology is considered congenital. The patients had dyspnea, fatigue, atrial fibrillation, and pulmonary emboli. Pericardial taps were performed because of false diagnosis of pericardial effusion. Differential diagnosis from valvular heart disease is difficult.[1–3] Idiopathic dilation of both atria is extremely rare.[4] In addition to all these complications, dilation of both atria may also be asso-

From the Heart Institute, Chaim Sheba Medical Center, Tel-Hashomer and Sackler School of Medicine, Tel-Aviv University, Ramat-Aviv, Israel.
Manuscript received April 26, 1983, accepted May 10, 1983.

ciated with systemic embolization. We report the first case of this anomaly diagnosed antemortem.

A 24-year-old pregnant woman was referred to us because of progressive dyspnea. At age 20 years, atrial fibrillation had developed. Delivery occurred at 8 months of pregnancy. Two weeks later transient left hemiparesis developed. No signs of congestive heart failure or cyanosis were found. The heart rate was irregular (80 beats/min). Blood pressure was 110/60 mm Hg. Both heart sounds were accentuated and the second sound was not split. A systolic murmur (grade 1/6) was heard over the upper left sternal border. A short mid-diastolic murmur was heard over the apex. The electrocardiogram showed atrial fibrillation and left-axis deviation. The thoracic roentgenogram showed cardiac enlargement, mainly due to enlargement of both atria. The pulmonary artery segment was prominent. Echocardiography demonstrated marked dilation of both atria. All cardiac valves were normal; however, a fine diastolic flutter of the anterior mitral leaflet was demonstrated. Radionuclide cardiac imaging demonstrated marked dilation of both atria, a left ventricular ejection fraction of 63%, and a right ventricular ejection fraction of 54%. Cardiac catheterization and angiocardiography confirmed biatrial dilation and revealed no shunt or obstructive lesion. Ventricular anatomy and contractility were normal, and so were the pressures in the cardiac chambers and great arteries. No signs of thrombus were seen. Routine laboratory tests including thyroid function tests revealed no abnormal findings.

The etiology of idiopathic biatrial dilation is unclear. Studies of idiopathic dilation of the right atrium revealed a partial loss of atrial muscular fibers, irregular thickening of muscle fibers, lipomatous degeneration and lymphocytic infiltration of the atrial wall, and no signs of rheumatic heart disease. Congenital etiology or changes after myocarditis were suggested by most investigators[1,2,5,6] to explain the pathogenesis.

Acute Myocardial Infarction 14 Years After an Acute Episode of Kawasaki's Disease

MOSHE Y. FLUGELMAN, MD
YONATHAN HASIN, MD
MAYER M. BASSAN, MD
RON LEOR, MD
MERVYN S. GOTSMAN, MD

Kawasaki's disease is an acute febrile illness of young children.[1] Coronary artery aneurysms have been described in 15% of patients during the acute disease.[2] Death attributed to occlusion or rupture of coronary artery aneurysms occurs in 1 to 2% of patients.[3] Symptomatic coronary artery involvement usually occurs within months of the acute disease and rarely presents for the first time in adults.[2–4] Such was not the case in the patient described herein.

From the Department of Cardiology, Hadassah University Hospital, Ein Kerem and the Department of Internal Medicine, Hadassah University Hospital, Mount Scopus, Jerusalem, Israel.

Manuscript received April 4, 1983, accepted April 21, 1983.

A 23-year old male smoker was hospitalized with retrosternal chest pain lasting 3 hours. Findings on physical examination were normal, but the electrocardiogram showed S-T segment depression in leads V_1 to V_4. Creatine phosphokinase (CPK) level on admission was 1,008 U/liter. The pain subsided rapidly, and the patient was asymptomatic for the next 10 days. Serial electrocardiograms demonstrated the development of small Q waves in leads II, III, and aVF, and the CPK level returned to normal. A graded effort test performed 10 days after admission was stopped after 5 minutes because of chest pain and S-T segment depression of 1.5 mm. Coronary angiography performed 14 days after

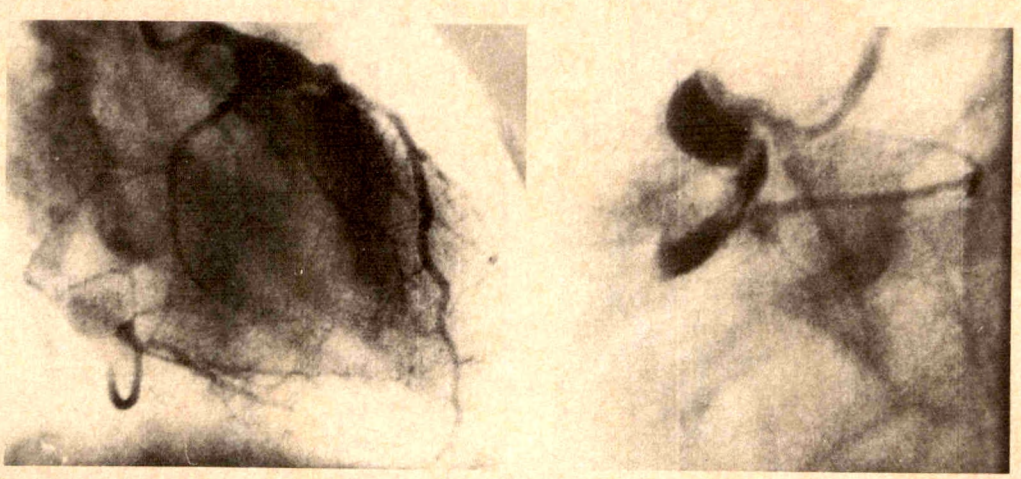

Figure 1. Left, left coronary artery injection (right anterior oblique view) showing a large aneurysm of the left main coronary artery extending to the left anterior descending and circumflex arteries. The distal right coronary artery is demonstrated (**bottom left** of photograph). The distal coronary arteries are normal. **Right,** right coronary artery injection (left anterior oblique view) showing a large aneurysm at the origin of the artery. Contrast material surrounds a big thrombus. No anterograde filling of the artery is demonstrated.

admission showed a large aneurysm of the left main coronary artery extending to the left anterior descending and left circumflex arteries. The distal right coronary artery filled from the left system (Fig. 1, left). A large aneurysm at the origin of the right coronary artery contained thrombus without anterograde filling of the vessel (Fig. 1, right). Ventriculography demonstrated good left ventricular function with a small area of hypokinesia in the inferior wall. The patient was discharged on warfarin and beta blockers and was scheduled for coronary bypass surgery.

At age 9 years, he had been hospitalized for a febrile episode associated with buccal ulceration, bilateral conjunctivitis, and disseminated rash. This had not improved with antibiotic treatment. After 5 weeks, the symptoms and signs had disappeared and the patient remained in good health without physical limitation until the present admission. Although the diagnosis of Kawasaki's disease had not been made at that time, the characteristic acute episode as well as the current typical angiographic findings were considered evidence that the patient had this disease.

Before angiography, the tentative etiologic diagnoses in this young adult were either coronary atherosclerosis associated with smoking[5] or possible coronary artery spasm due to heavy alcohol intake with normal coronary arteries.[6] The typical angiographic findings and the febrile illness at age 9 years provided sufficient evidence to diagnose Kawasaki's disease. The long interval between the acute disease and the first presentation of coronary artery involvement obscured the relation between the illness at age 9 years and the acute myocardial infarction at age 23. Our case illustrates the importance of coronary angiography in young adults with ischemic heart disease. In all young patients with ischemic heart disease, a careful search for a history compatible with Kawasaki's disease should be carried out.

Acknowledgment: We thank Dr. Basil S. Lewis for his help in evaluating this patient.

RELATION OF HIGH-INTENSITY EXERCISE TO RECURRENCE RATE OF MYOCARDIAL INFARCTION AND/OR CORONARY DEATH

We read the article by Rechnitzer et al[1] showing that high intensity endurance exercise does not reduce myocardial infarction (MI) rate or coronary death beyond activity that fails to produce a training effect. The results were not unexpected. Endurance exercise failed to reduce reinfarction and coronary death rates in another well-conceived postinfarction exercise trial.[2] The authors cite the multifactorial approach by Kallio et al,[3] which demonstrated a lower incidence of sudden death in postinfarction patients and included exercise in their intervention. However, exercise was probably not a factor in reducing sudden death, as the intervention group failed to demonstrate a training effect.

Epidemiologic investigators concerned with the mode of exercise and coronary disease have found that exercise other than the endurance type (i.e., share croppers[3] and longshoremen[4]) has resulted in reduced untoward cardiovascular events. The study by Paffenbarger and Hale[5] points out that only cargo handlers engaged in burst activities of pushing, pulling, and lifting cargo had a reduced incidence of sudden cardiac death. Other longshoremen not engaged in this form of activity did not show coronary benefit. In summary, endurance exercise has failed to produce beneficial results in prospective trials, and cardiovascular risk benefits are not well supported by epidemiologic research. It may be more important to train individuals in another manner. Burst activity utilizing resistance to the exercise (such as pushing, pulling, and lifting) may help provide answers to the question of exercise benefits in the prevention of coronary heart disease.

LEFT ISOMERISM (POLYSPLENIA SYNDROME) AND COMPLETE ATRIOVENTRICULAR BLOCK

Garcia et al[1] reported an apparent association between left isomerism and complete atrioventricular block. They presented a total of 9 cases of left isomerism and congenital complete AV block (4 cases of their own and 5 from the literature), and 2 cases of acquired nonsurgical complete AV block associated with left isomerism. To this experience we add 2 cases of congenital complete AV block and left isomerism, and additional published evidence to support the association between complete AV block and left isomerism.

A 2.5-kg, 36-week gestation infant was transferred to our hospital at 1 hour of age for management of hydrops fetalis and complete AV block, which had been diagnosed in utero elsewhere. Cardiac catheterization at 12 hours of age showed double-outlet right ventricle, D-transposition of the great arteries, common atrium, partial anomalous pulmonary venous return to the right side of the common atrium, patent ductus arteriosus, interrupted inferior vena cava with continuation to the azygos system, and abdominal heterotaxia. The electrocardiogram showed complete AV block and superior axis of the P wave. A temporary transvenous ventricular pacing catheter was placed after cardiac catheterization. Digoxin and diuretic therapy was begun. One week later, at a postdiuresis weight of 2.2 kg, a permanent epicardial demand ventricular pacemaker was implanted and the patent ductus arteriosus was ligated. A technetium liver-splenic scan confirmed the presence of splenic tissue. The patient did well postoperatively, and remains well at 15 months of age.

The second patient was born by Cesarean section for fetal bradycardia at 38 weeks' gestation. At birth hydrops fetalis, respiratory distress, and a ventricular rate of 65 beats/min were noted. The electrocardiogram showed complete AV block and superior axis of the P wave, a diagnostic sign of polysplenia syndrome.[2] The chest x-ray showed mesocardia, cardiomegaly, bilateral hyparterial bronchi, increased pulmonary vascularity, and abdominal heterotaxia. She died at 24 hours of age with intractable heart failure.

In addition to our personal experience, 3 additional cases are reported in the literature. Shenker[3] reported a case of intrauterine complete heart block and polysplenia syndrome. The infant died at 2 weeks of age, and necropsy showed atrial septal defect, ventricular septal defect, anomalous pulmonary venous return, and multiple spleens. Sokol et al[4] reported a case of intrauterine complete heart block and polysplenia syndrome. This infant (33 weeks' gestation) died 28 hours after birth, and necropsy showed endocardial cushion defect and interrupted inferior vena cava with continuation to the azygos system. Morphologic examination of the conduction system disclosed fibrosis in the atrium and AV node. Kleinman et al[5] reported a case of congenital complete AV block (diagnosed by fetal echocardiography) and polysplenia syndrome. This infant was born at 34 weeks' gestation and had hydrops fetalis, levocardia, and endocardial cushion defect. This infant died 10 minutes after birth.

As did Garcia et al,[1] we emphasize that left isomerism with complex cardiac defects is often associated with complete AV block. Also, this association should be recognized as the most common cause of death in infants with congenital complete AV block. Since cardiac anomalies in left isomerism are often amenable to surgery, aggressive management is warranted. The potential results are demonstrated by our first patient who, to our knowledge, is the smallest infant to accept a permanent epicardial pacemaker. This infant is the only one reported with left isomerism and congenital complete heart block surviving past 1 year of age. In the Garcia et al[1] series, all 4 newborns with congenital heart block died by age 2 months. With the existence of perinatal centers and availability of fetal echocardiography, this complex cardiac disease should be diagnosed in utero.

BYPASS GRAFTING IN TOTAL OCCLUSION OF THE LEFT MAIN CORONARY ARTERY

I have read the article by Esente et al[1] about coronary collateral protection. My purpose in responding is to point out that present-day treatment would have been more aggressive in revascularizing their patient. Although at 32 months the patient is reported to be asymptomatic, it has been demonstrated that long-term survival and symptomatic relief are limited by diseased ungrafted coronary arteries.

The 2 arteriographic frames presented illustrate a 100% left main occlusion, a 70 to 80% mid-left anterior descending (LAD) stenosis, and a 50% right coronary artery stenosis. The proximal anatomy is cut off on the frame, but it appears that a dominant diagonal would definitely not be satisfactorily revascularized from the LAD nor from the left circumflex graft. A 50% stenosis in the right coronary artery warrants grafting at the

time of left-sided revascularization. With present-day myocardial protection, complete revascularization has been greatly simplified and complete revascularization is usually necessary.

UNSTABLE ANGINA PECTORIS: CORRECTION OF ERROR IN PREVIOUS REPORT

In our report on the management of unstable angina,[1] we stated that 77 of our 100 cases followed up for 1 year remained free of "significant symptoms." This should have read "significant complications." In fact, 36 of the 96 28-day survivors complained of angina pectoris during some or all of the follow-up period.

This error in the text of our report has given rise to misunderstanding and to questions about the comparability of our diagnostic criteria with those of other studies.[2] We would like to confirm that our diagnostic criteria conform closely to those of the Framingham Study[3] and the National Cooperative Study Group.[4]

This correction had already been conveyed to the previous Editor of the *Journal* but failed to be published because of the change in journal management.

TRANSMURAL VERSUS NONTRANSMURAL MYOCARDIAL INFARCTION

We are surprised that, for one so obsessed with semantic clarity, Dr. Spodick chose to use a quotation from our article so loosely and out of context in order to strengthen his own argument for discarding the terms "transmural" and "nontransmural (subendocardial)" for classifying acute myocardial infarction.[1] In making the statement "regardless of the terms used . . . ," we were not suggesting that terminology should be disregarded or is unimportant. Rather, we were making the point that *whatever* terminology is used, it was our experience that patients with infarcts manifested by Q waves differed from those without Q waves. The full text of that segment of our paper reads: "Spodick has suggested that infarcts should be designated according to the presence or absence of Q waves and not by the traditionally used terms of subendocardial or nontransmural. Regardless of the terms used, our studies and those of other investigators suggest that, at least clinically, the absence of Q waves in patients with acute myocardial infarction appears to identify a group whose immediate and subsequent clinical courses differ from those of patients with Q waves."[2] I should point out in all fairness that not everybody agrees with even this statement![3]

If a distinction is to be made, I submit that "Q wave infarct" and "non–Q wave infarct" are more comprehensive than Spodick's classification of Q wave infarction and S-T infarction. Although it is rare, it is possible to have myocardial infarction with neither Q waves nor S-T segment abnormalities showing on the standard electrocardiogram.

Roman W. DeSanctis, MD
Adolph M. Hutter, Jr., MD
Boston, Massachusetts

1. **Spodick DH.** Q wave infarction versus S-T infarction: nonspecificity of electrocardiographic criteria for differentiating transmural and nontransmural lesions. Am J Cardiol 1983;51:913–915.
2. **Hutten AM Jr, DeSanctis RW, Flynn T, Yeatman LA.** Nontransmural myocardial infarction: a comparison of hospital and late clinical course of patients with that of matched patients with transmural anterior and transmural inferior myocardial infarction. Am J Cardiol 1981;48: 595–602.
3. **Phibbs BD.** "Transmural" versus "Subendocardial" myocardial infarction: an electrocardiographic myth. J Am Coll Cardiol 1983;1:561–564.

REPLY: DeSanctis and Hutter posit 3 considerations: (1) appropriate quotation, (2) results of their studies, and (3) improved terminology. They have contributed their complete quotation so that the readers can decide for themselves whether the material quoted was—for the purpose intended—out of context. It certainly was not loosely chosen. My own complete quotation was: "Indeed, investigators of the highest intellect and skill—despite *explicitly acknowledging the material cited in References 1–3*,—write 'regardless of the terms used . . . ,' implying that slipshod terminology is unimportant." This formulation was designed to simultaneously acknowledge their work (emphasis added) and isolate the point of my essay—disregard for accurate labels—with the elision indicating incomplete quotation. References 1 to 3 referred to my letters in 3 journals in 1980, 1981, and 1982, extensively documenting the lack of correlation between electrocardiography and anatomy. Because letters were ineffective, it was (as the editor can confirm) their report that finally led to a more formal attempt to set things right. DeSanctis and Hutter have missed the point of my essay; terminology was in question, never their scientific material, and I hope my quotation of Confucius (p. 914) set the tone.

I hope these efforts make clear that my concern is with *conceptual* clarity—which appropriate terminology can either enhance or debase (Cf. Confucius). The important thing is to call things as we see them. What we *actually see* on the ECG is how we should label an infarct, keeping in mind that the ECG cannot tell us the anatomic extent of the infarct, but is telling us something else that should require further investigation. The data in their paper is a meticulous contribution to the distinction between Q wave and non–Q wave infarcts. Indeed, it should further stimulate those who wish to learn why the ECG separates infarcts into certain clinical and prognostic groups, but cannot reliably distinguish their anatomy. Finally, DeSanctis and Hutter have improved my classification by mentioning that the rare possibility of infarction with neither Q waves nor S-T segment abnormalities could not be called S-T infarction (although the vast number of non-Q wave infarcts can be). I believe I can make their proposal even more comprehensive. Like our colleagues who distinguish A, B, and "non-A non-B" hepatitis, perhaps we could designate Q, S-T, and "non-Q non-S-T" infarctions.

Worcester, Massachusetts

MYOCARDIAL METABOLIC ALTERATIONS AFTER CONTRAST ANGIOGRAPHY

The article by Wisneski et al[1] demonstrated that contrast medium alters the myocardial uptake of various substrates. Their results suggested that the changes in myocardial uptake of lactate and glucose could be related to a decrease of the arterial level of free fatty acids induced by the contrast medium. The authors mentioned, however, that all patients received heparin (10,000 U) as an intravenous bolus before the arterial puncture. Heparin has a lipolytic effect and induces a release of free fatty acids with an initial increase of this substrate, followed by a decrease. Thus, how much time elapsed between the administration of heparin and the first sampling point?

The authors mentioned that blood samples were obtained at 3 and 10 minutes to ensure a steady metabolic state, but one can suspect that these 2 samples could concern 2 points symmetrically located on the ascending and descending branch of the peak after the injection of heparin.

Another point concerns the expression of the results. These were presented in terms of myocardial uptake, i.e., the product of coronary sinus blood flow by arteriovenous difference of the substrate. Their Figure 8 suggests a transient increase of coronary sinus blood flow. What happened to the arteriovenous difference? Does the contrast medium convert a normal myocardial extraction (A > V) of lactate in a production (V > A) of lactate, usually considered a metabolic marker of ischemia?

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Prescribing Information Tablets of 50 mg
Tablets of 100 mg

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

experts agree the preference for one beta-receptor over the other is not absolute.

CME Test #2

Coronary Reperfusion and Bezold-Jarisch Reflex*

The University of Alabama School of Medicine designates this continuing medical education activity for 1 credit hour in Category 1 of the Physician's Recognition Award of the American Medical Association. Answers are to be marked on the instruction sheet on page A135.

1. The Bezold-Jarisch reflex is characterized by:
   a) tachycardia and hypertension
   b) bradycardia and hypertension
   c) tachycardia and hypotension
   d) bradycardia and hypotension

2. It is known that the receptors that induce the Bezold-Jarisch reflex respond to:
   a) chemical stimuli
   b) mechanical stimuli
   c) metabolic stimuli
   d) all the above

3. The exact location of the receptors in man has:
   a) been primarily in the inferoposterior wall
   b) not been determined experimentally
   c) been primarily in the inferoanterior wall
   d) been in none of the above

4. In this study, arteriographic findings identified occlusions in:
   a) left anterior descending arteries of 44 cases
   b) right coronary arteries of 7 cases
   c) left circumflex coronary arteries of 13 cases
   d) all the above

5. In this study, recanalization of the occluded coronary arteries was achieved in:
   a) 34 of 40 right coronary arteries
   b) 34 of 40 left anterior descending arteries
   c) 23 of 32 left anterior descending arteries
   d) none of the above

6. In this study, it is noteworthy that in 19 of 20 cases, the Bezold-Jarisch reflex was associated with involvement of the:
   a) left anterior descending artery
   b) left circumflex coronary artery
   c) right coronary artery
   d) none of the above

7. The only occurrence of the Bezold-Jarisch reflex associated with left anterior descending recanalization was observed when this artery was the source of collateral blood flow to:
   a) an occluded right coronary artery
   b) an arterial aneurysm
   c) an occluded left circumflex coronary artery
   d) an occluded left anterior descending artery

8. On first measurements, in the representative case involving a 72-year-old man, there was:
   a) 190/26 mm Hg right ventricular pressure
   b) 190/26 mm Hg aortic pressure
   c) 188/82 mm Hg aortic pressure
   d) 188/82 mm Hg left ventricular pressure

9. This study confirmed that myocardial reperfusion is capable of:
   a) stimulating a cardiac inhibitory reflex
   b) stimulating a cardiac excitatory reflex
   c) offsetting effects of hypertensive medication
   d) causing tachycardia

10. In this study, the factor that initiates the Bezold-Jarisch reflex appears to be:
    a) neurotransmitted
    b) chemical
    c) mechanical
    d) metabolic

11. Observations in this study suggest that the occurrence of the Bezold-Jarisch reflex after coronary reperfusion is:
    a) a reliable predictor of myocardial salvage
    b) not a reliable predictor of myocardial salvage
    c) what is expected of prolonged ischemia
    d) none of the above

12. Because a vagal reflex induces hypotension and bradycardia after right coronary recanalization, it is advisable to:
    a) administer atropine prophylactically
    b) remove patient from oxygen tent quickly
    c) administer aminophylline prophylactically
    d) administer amytryptoline prophylactically

***This article appears on page 221 of this issue.**

Your angina patients* can become more active now...with PROCARDIA protection. They'll be pain-free more of the time[1] and find their need for nitroglycerin greatly reduced.[2] They'll be able to work harder, exercise more.[3] And be more active participants in their own lives once again.

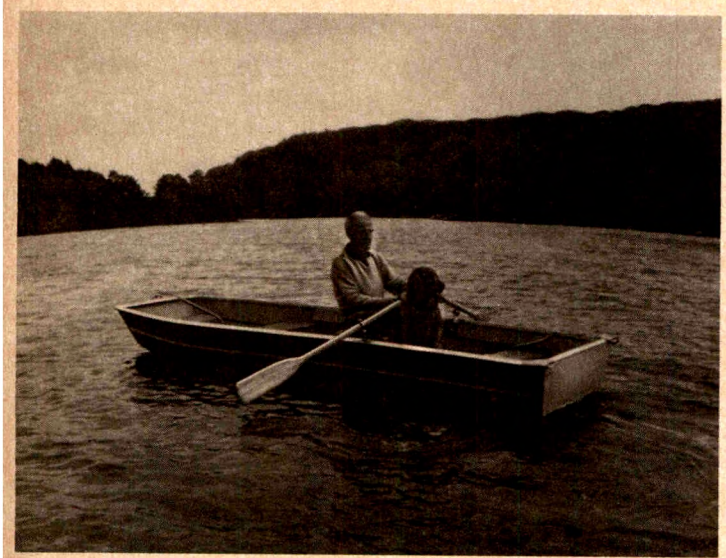
feeling better...doing more

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

*Procardia is indicated for the management of:

- Confirmed vasospastic angina.
- Angina where the clinical presentation suggests a possible vasospastic component.
- Chronic stable angina without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or nitrates or who cannot tolerate these agents. In chronic stable angina (effort-associated angina) Procardia has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these

feeling better...doing more



PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

–Usual effective dosage is 30-60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because Procardia decreases peripheral vascular resistance, careful monitoring of blood pressure during initial administration and titration is suggested. Close observation is especially recommended for patients taking medication known to lower blood pressure.

–Offers a favorable safety profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

BRIEF SUMMARY
PROCARDIA® CAPSULES For Oral Use
(nifedipine)

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in those patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Carcinogenesis, mutagenesis, impairment of fertility: When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose.

Pregnancy: Category C. Please see full prescribing information with reference to teratogenicity in rats, embryotoxicity in rats, mice and rabbits, and abnormalities in monkeys.

ADVERSE REACTIONS: The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, diarrhea, constipation, inflammation, joint stiffness, shakiness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, and sexual difficulties. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

Laboratory Tests: Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms. Cholestasis, possibly due to PROCARDIA therapy, has been reported twice in the extensive world literature.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the man-

Continued availability with the same high quality.

If you depended on Picker International or American Optical Medical Division for Patient Monitoring Instrumentation, you'll want to know about Pioneer Medical Systems. We are the new source for the full, familiar line of monitoring instruments and systems you've come to trust. Instruments for patient monitoring, telemetry, cardioresuscitation, Holter and computerized arrhythmia monitoring systems (CAMS)—they're now all available from Pioneer Medical Systems.

Pioneer Medical Systems is growing to serve you. We are the leading supplier of emergency medical services communication systems in the U.S. and in many parts of the world.

The acquisition of the Patient Monitoring Division of Picker International by Pioneer Medical Systems and the establishment of our Instruments Group, proudly demonstrates our continuing support to the health care community.

The source is new, but the product reliability and the commitment to service continues. Pioneer Medical Systems. Think of us when you need CAMSCAN, SPECTRA, PULSAR 4, DURA VUE, LOWN CARDIOVERTER, LOWN TRENDSCRIBER, or CAMS.

For product information, assistance and the location of your local Pioneer Medical Systems representative, call Michael Sokol, Vice President, toll free **1-800-343-1450,** extension 235.

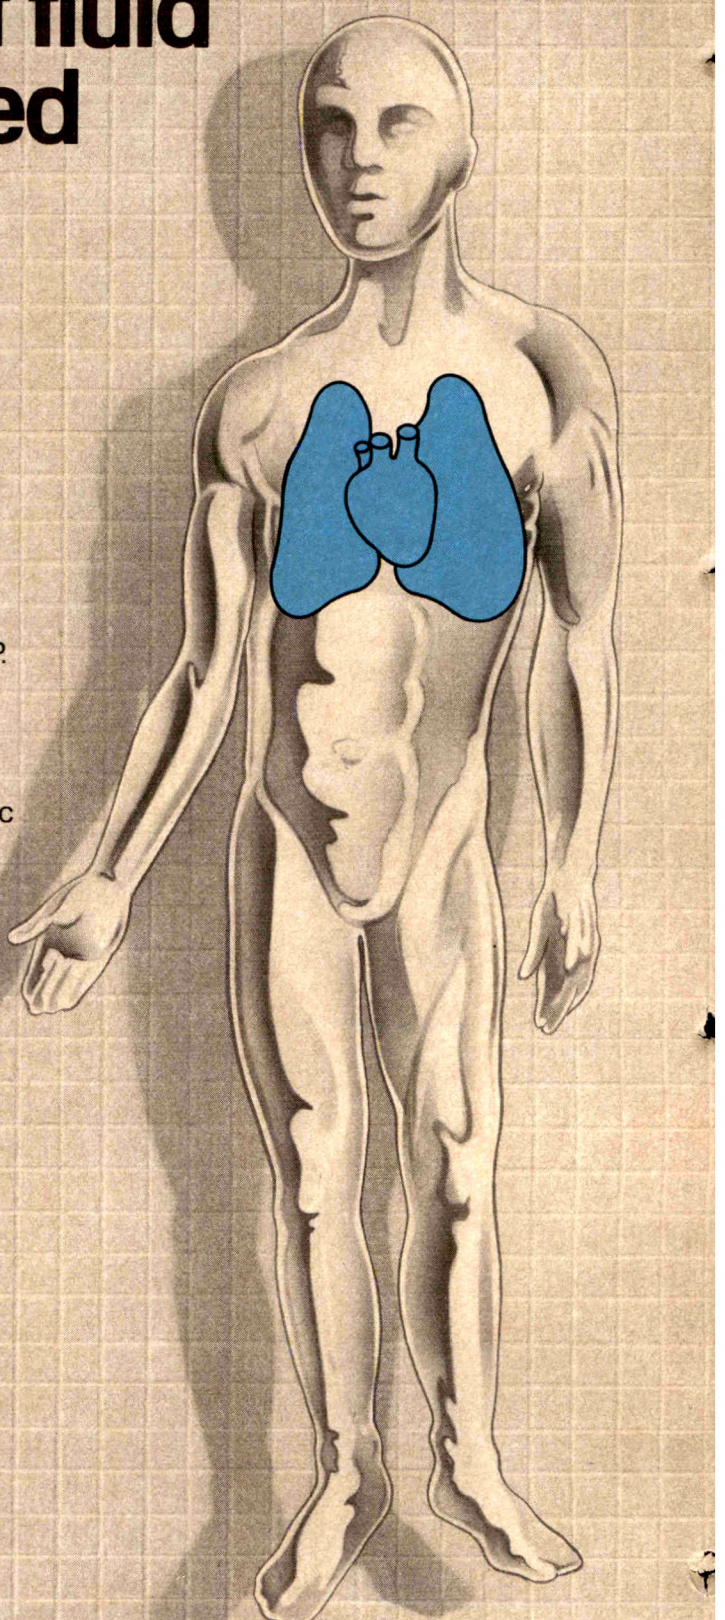
Therapeutic challenge:

Redistribution of fluid in CHF associated with acute MI



In Early CHF[1]

Pulmonary congestion with increased preload.

Findings: Elevated preload, elevated blood pressure, normal or slightly decreased cardiac output, PCWP greater than or equal to 18 mm Hg.

Therapeutic goal:
Reduce pulmonary congestion, lower PCWP to 15 to 18 mm Hg.

In Late CHF[1]

Pulmonary congestion with increased preload and afterload.

Findings: Low cardiac output, depressed blood pressure, and high PCWP.

Therapeutic goal:
Reduce pulmonary congestion, preload, and afterload, increase cardiac output, and lower PCWP to 15 to 18 mm Hg.

Why wait for the patient to become unresponsive to traditional diuretic/digitalis therapy?

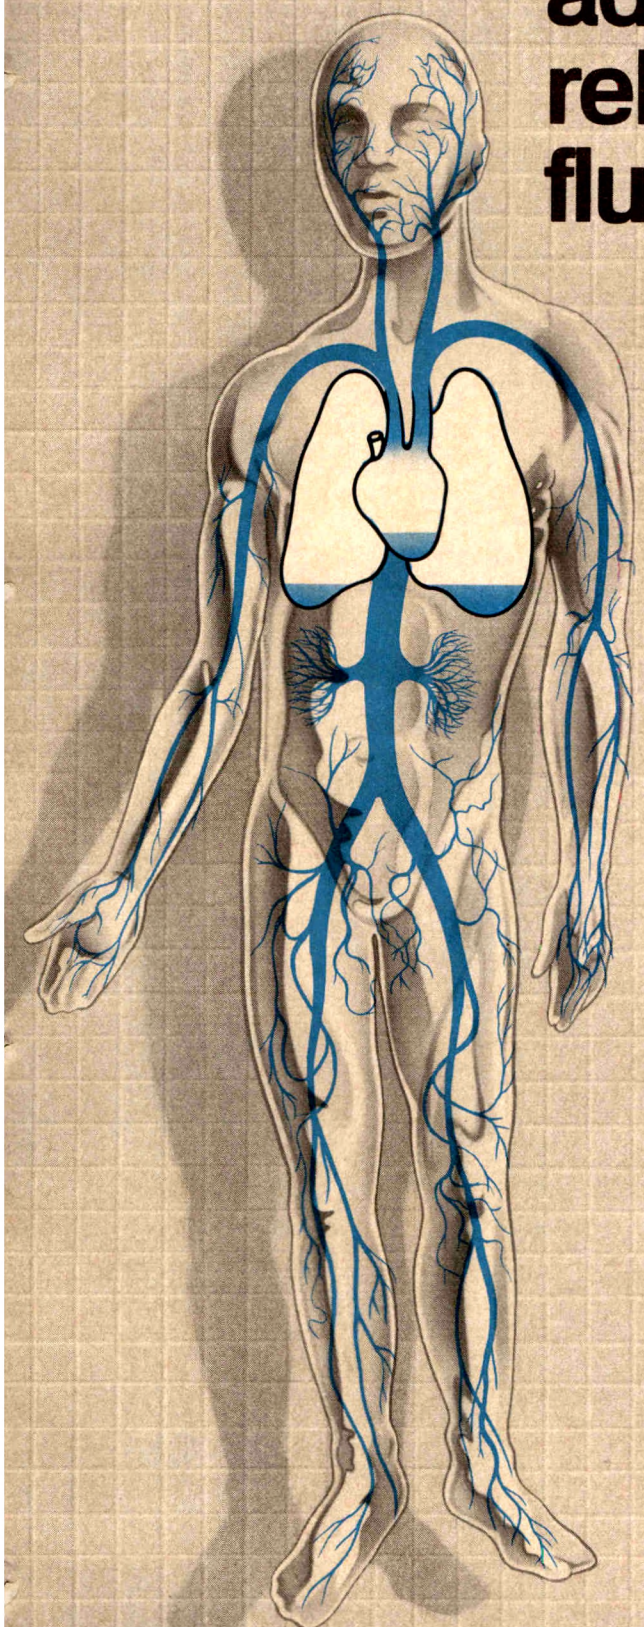
Division of American Hospital Supply Corporation

Give Tridil (nitroglycerin) adjunctively to help relieve the fluid-burdened heart



In a dose-related manner, Tridil produces dilation of both arterial and venous beds—for a therapeutic redistribution of fluid.

Suggested therapy in early CHF

If blood pressure is normal:
Tridil to reduce preload and PCWP. Diuretics to decrease fluid volume.

If blood pressure is elevated:
Tridil should be initiated immediately to decrease preload, PCWP, and blood pressure, while maintaining coronary perfusion.

Suggested therapy in late CHF

If blood pressure is normal or only moderately depressed:
Vasopressors and Tridil adjunctively, with continuous hemodynamic monitoring.

If blood pressure is significantly depressed:
Vasopressors and Tridil adjunctively to reduce preload, afterload, and PCWP. Dopamine to increase the contractility of the myocardium. PCWP should be monitored.

Use of nonabsorbing Tridilset®

Sorptive loss of Tridil may range up to 80% when infused through a conventional PVC administration set[2] To overcome this problem, administer Tridil through Tridilset administration set or Tridilset V.I.P.™ volumetric pump connector set.

The most frequent adverse reaction in patients treated with Tridil is headache. Please see the following page for a brief summary of prescribing information. Note: Tridil is a potent drug and must be diluted before infusion.

For additional information, contact the Medical Services Department, American Critical Care, division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, IL 60085, Phone 312/473-3000.

2. Baaske DM, et al: Administration set suitable for use with intravenous nitroglycerin. *Am J Hosp Pharm* 1982;39:121-122.

TRIDIL® (nitroglycerin) SYSTEM

American Critical Care

NOT FOR DIRECT INTRAVENOUS INJECTION. TRIDIL® MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION (SEE DOSAGE AND ADMINISTRATION SECTION OF FULL PRESCRIBING INFORMATION). THE ADMINISTRATION SET USED FOR INFUSION WILL AFFECT THE AMOUNT OF TRIDIL DELIVERED TO THE PATIENT. (SEE WARNINGS, AND DOSAGE AND ADMINISTRATION SECTIONS.)

CAUTION

SEVERAL PREPARATIONS OF NITROGLYCERIN FOR INJECTION ARE AVAILABLE. THEY DIFFER IN CONCENTRATION AND/OR VOLUME PER VIAL. WHEN SWITCHING FROM ONE PRODUCT TO ANOTHER ATTENTION MUST BE PAID TO THE DILUTION AND DOSAGE AND ADMINISTRATION INSTRUCTIONS.

CONTRAINDICATIONS

TRIDIL should not be administered to individuals with:

1. A known hypersensitivity to nitroglycerin or a known idiosyncratic reaction to organic nitrates.
2. Hypotension or uncorrected hypovolemia, as the use of TRIDIL in such states could produce severe hypotension or shock.
3. Increased intracranial pressure (e.g., head trauma or cerebral hemorrhage).
4. Constrictive pericarditis and pericardial tamponade.

WARNINGS

1. Nitroglycerin readily migrates into many plastics. To avoid absorption of nitroglycerin into plastic parenteral solution containers, the dilution and storage of TRIDIL for intravenous infusion should be made only in *glass* parenteral solution bottles.
2. Some filters absorb nitroglycerin; they should be avoided.
3. Forty to 80% of the total amount of nitroglycerin in the final diluted solution for infusion is absorbed by the polyvinyl chloride (PVC) tubing of the intravenous administration sets currently in general use. The higher rates of absorption occur when flow rates are low, nitroglycerin concentrations are high, and the administration set is long. Although the rate of loss is highest during the early phase of infusion (when flow rates are lowest) the loss is neither constant nor self-limiting; consequently no simple calculation or correction can be performed to convert the theoretical infusion rate (based on the concentration of the infusion solution) to the actual delivery rate.

Because of this problem, American Critical Care has developed TRIDILSET,® an administration set in which loss of TRIDIL is minimal (less than 1%). TRIDILSET (or a similar administration set) is recommended for infusions of TRIDIL.

DOSING INSTRUCTIONS MUST BE FOLLOWED WITH CARE. IT SHOULD BE NOTED THAT WHEN TRIDILSET IS USED, THE CALCULATED DOSE WILL BE DELIVERED TO THE PATIENT BECAUSE THE LOSS OF TRIDIL DUE TO ABSORPTION IN STANDARD PVC TUBING WILL BE KEPT TO A MINIMUM. NOTE THAT THE DOSAGES COMMONLY USED IN PUBLISHED STUDIES UTILIZED GENERAL-USE PVC ADMINISTRATION SETS AND RECOMMENDED DOSES BASED ON THIS EXPERIENCE ARE TOO HIGH WHEN TRIDILSET IS USED.

PRECAUTIONS

TRIDIL (nitroglycerin) should be used with caution in patients with severe liver or renal disease.

Excessive hypotension, especially for prolonged periods of time, must be avoided because of possible deleterious effects on the brain, heart, liver, and kidney from poor perfusion and the attendant risk of ischemia, thrombosis, and altered function of these organs. Paradoxical bradycardia and increased angina pectoris may accompany nitroglycerin-induced hypotension. Patients with normal or low pulmonary capillary wedge pressure are especially sensitive to the hypotensive effects of TRIDIL. If pulmonary capillary wedge pressure is being monitored, it will be noted that a fall in wedge pressure precedes the onset of arterial hypotension, and the pulmonary capillary wedge pressure is thus a useful guide to safe titration of the drug.

Carcinogenesis, mutagenesis, impairment of fertility

No long-term studies in animals were performed to evaluate carcinogenic potential of TRIDIL.

Pregnancy

Category C. Animal reproduction studies have not been conducted with TRIDIL. It is also not known whether TRIDIL can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. TRIDIL should be given to a pregnant woman only if clearly needed.

Nursing Mothers

It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TRIDIL is administered to a nursing woman.

Pediatric Use

The safety and effectiveness of TRIDIL in children have not been established.

ADVERSE REACTIONS

The most frequent adverse reaction in patients treated with TRIDIL is headache, which occurs in approximately 2% of patients. Other adverse reactions occurring in less than 1% of patients are the following: tachycardia, nausea, vomiting, apprehension, restlessness, muscle twitching, retrosternal discomfort, palpitations, dizziness and abdominal pain.

The following additional adverse reactions have been reported with the oral and/or topical use of nitroglycerin: cutaneous flushing, weakness, and occasionally drug rash or exfoliative dermatitis.

OVERDOSAGE

Accidental overdosage of TRIDIL may result in severe hypotension and reflex tachycardia which can be treated by elevating the legs and decreasing or temporarily terminating the infusion until the patient's condition stabilizes. Since the duration of the hemodynamic effects following TRIDIL administration is quite short, additional corrective measures are usually not required. However, if further therapy is indicated, administration of an intravenous alpha adrenergic agonist (e.g., methoxamine or phenylephrine) should be considered.

DOSAGE AND ADMINISTRATION

(For complete information, please see Full Prescribing Information)

NOT FOR DIRECT INTRAVENOUS INJECTION

TRIDIL IS A CONCENTRATED, POTENT DRUG WHICH MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION. TRIDIL SHOULD NOT BE ADMIXED WITH OTHER DRUGS.

Some patients with normal or low left ventricular filling pressures or pulmonary capillary wedge pressure (e.g., angina patients without other complications) may be hypersensitive to the effects of TRIDIL and may respond fully to doses as small as 5 mcg/min. These patients require especially careful titration and monitoring.

There is no fixed optimum dose of TRIDIL. Due to variations in the responsiveness of individual patients to the drug, each patient must be titrated to the desired level of hemodynamic function. Therefore, continuous monitoring of physiologic parameters (e.g., blood pressure and heart rate in all patients, other measurements such as pulmonary capillary wedge pressure, as appropriate), MUST BE PERFORMED to achieve the correct dose. Adequate systemic blood pressure and coronary perfusion pressure must be maintained.

HOW SUPPLIED

NDC 0094-0090-05, 25 mg-5 ml ampul. NDC 0094-0090-10, 50 mg-10 ml ampul. Each ml contains 5 mg nitroglycerin. Protect from freezing.

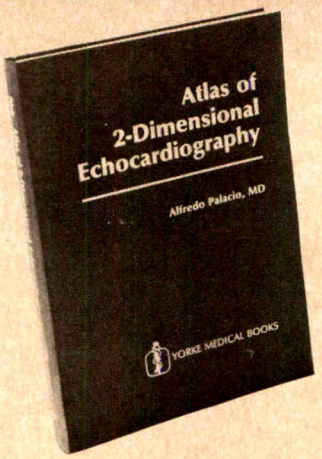
2-D Echocardiography Ever Published



Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School; Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $65.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

QUINTON TAKES THE TREADMILL THREE STEPS AHEAD.

There's a new standard for treadmill excellence. Not surprisingly, it comes from the company who has set treadmill standards for nearly 20 years. Quinton raises its own mark with the Q series—a new breed of treadmills and controller.

The Q-55. Tomorrow's treadmill today.

The Q-55 doesn't just set the pace. It advances the state-of-the-art to a whole new level.

No treadmill has ever been quieter. A Quinton breakthrough makes this the quietest transmission on record.

No treadmill has ever been more solid. The Q-55 will level itself. (See for yourself. Slide a book under one leg.) And its new, larger drums offer superb tracking.

No treadmill has ever been more functional. Its sleek, low-profile design gives the runner more room to maneuver. And every surface is designed for easy care.

The Q-65. Engineered to be a workhorse.

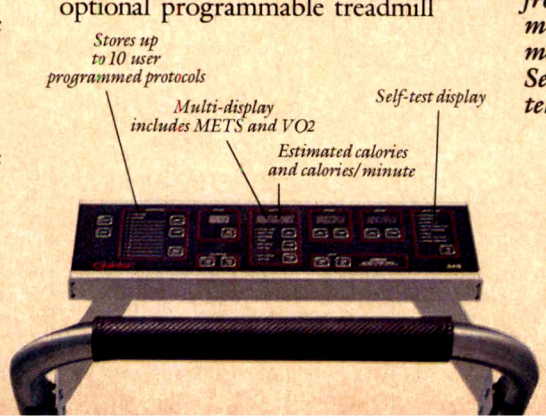
For heavy-duty demands, Quinton created a heavy-duty performer: the Q-65. Its longer length and three-horsepower motor make it ideal for rigorous testing or training.

And like its smaller brother, the Q-65 is built to give you top quality performance year after year.

The 645. Smart treadmill control.

Now you've seen the muscle, meet the brains: Quinton's 645, our optional programmable treadmill controller. Advanced microprocessor technology make it the most sophisticated controller ever available.

Its "smart" electronics let it store up to ten user programmed protocols—each with up to 99 different stages. It can calculate METS and VO^2, plus calories per minute and cumulative calories. It even tells you when something's wrong. And its human-engineered panel makes it extraordinarily simple to operate.



The Q Series from Quinton. Treadmill technology that's out front—but not out of reach. Find out more. Call or write Quinton Instrument Company, 2121 Terry Ave., Seattle, WA 98121, 1-800-426-0347, telex 328840. Distributed worldwide.

Your patients deserve the best ECG analysis they can get.

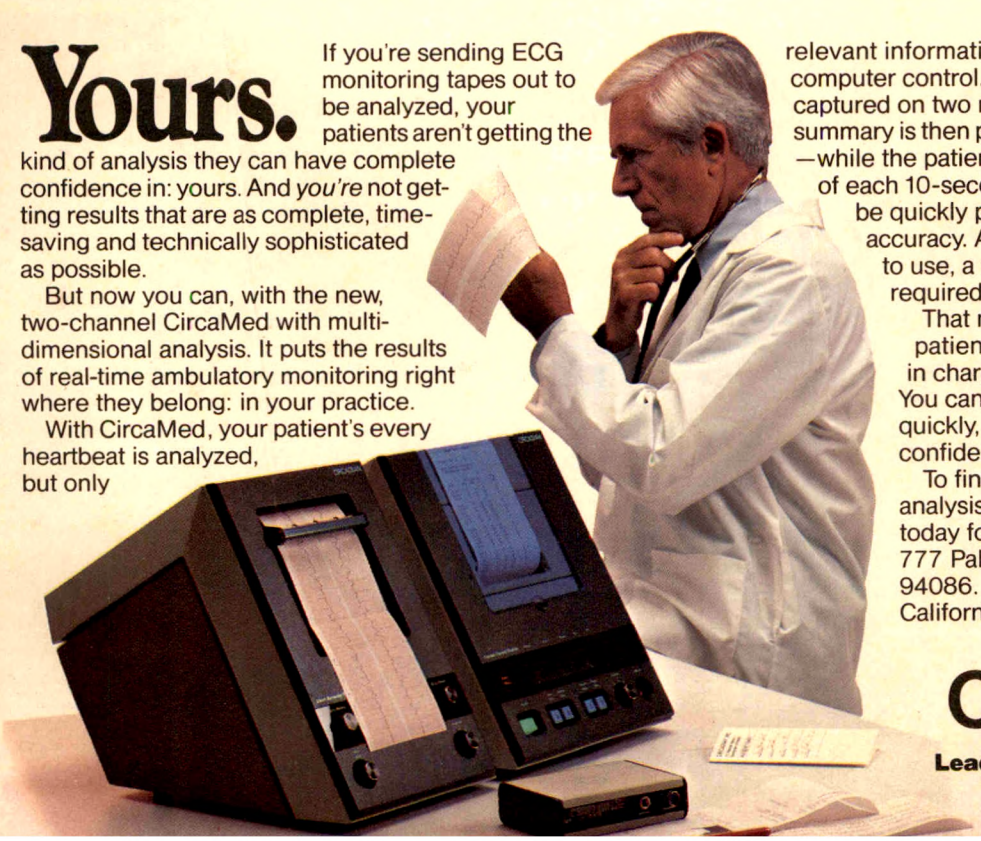
Yours. If you're sending ECG monitoring tapes out to be analyzed, your patients aren't getting the kind of analysis they can have complete confidence in: yours. And *you're* not getting results that are as complete, time-saving and technically sophisticated as possible.

But now you can, with the new, two-channel CircaMed with multi-dimensional analysis. It puts the results of real-time ambulatory monitoring right where they belong: in your practice.

With CircaMed, your patient's every heartbeat is analyzed, but only relevant information is recorded, under micro-computer control. Up to two days of patient data are captured on two multi-dimensional channels; a summary is then printed in your office within minutes —while the patient is still there. A strip chart record of each 10-second ECG measurement can also be quickly produced for further diagnostic accuracy. And because CircaMed is simple to use, a specially trained technician isn't required.

That means now neither you nor your patients have to worry about who's in charge of their ECG analysis: you are. You can both count on getting results quickly, economically and with complete confidence.

To find out how easy it is to bring ECG analysis into your practice, write us today for a brochure or demonstration: 777 Palomar Avenue, Sunnyvale, CA 94086. Or call: (800) 538-1772. In California (408) 738-8550.



CIRCADIAN

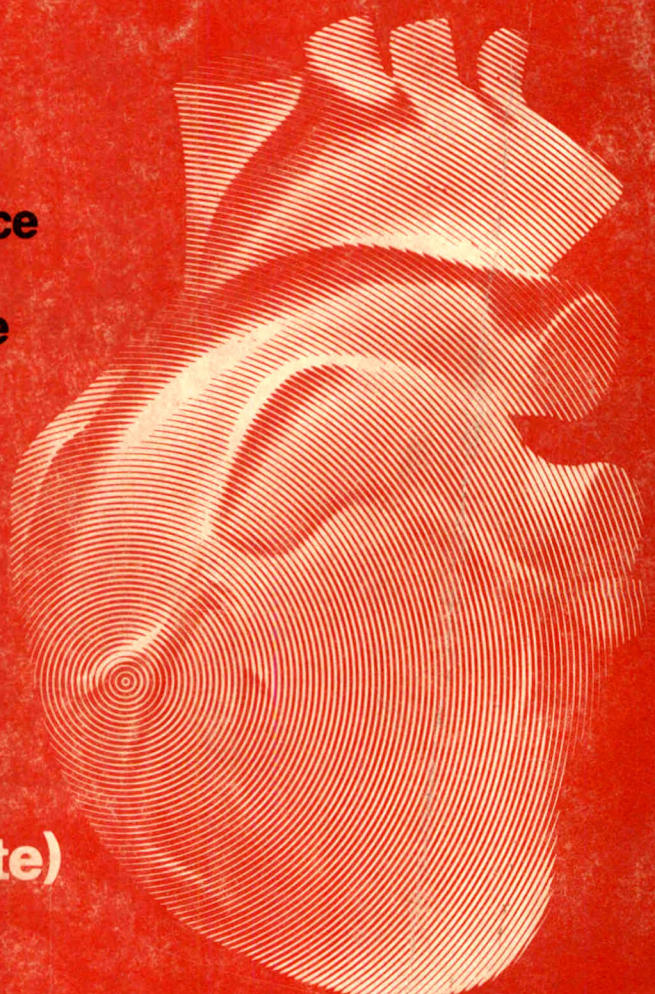
Leaders in real-time ECG analysis.

The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.



CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

NDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after pontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment f premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V unctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when herapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete eartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, omplete bundle branch block or other severe intraventricular conduction defects, myasthenia ravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial brillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by rogressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high entricular rate. This potential hazard may be reduced by digitalization prior to administration of uinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered oncurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence f quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or entricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or lose clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by otassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme aution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used ith caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting enal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in lasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be dministered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and etermination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are dministered. Periodic blood counts and liver and kidney function tests should be performed during ng-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations.
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digoxin (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: The drug should be used with caution due to excretion of the quinidine in breast milk. ADVERSE REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/or disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTESTINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricular tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMATOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intense pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribing Information.

Symposium on High-Density Lipoproteins and Coronary Artery Disease: Effects of Diet, Exercise, and Pharmacologic Intervention

ANTONIO M. GOTTO, Jr., MD, DPhil, Guest Editor

Opening Remarks

GUNTER SCHLIERF, MD, Co-Chairman

The high-density lipoproteins (HDL) for a quarter of a century were a rather neglected member of the lipoprotein family, but during recent years have become the favorite occupation in many laboratories. Occasionally, interpretation of research findings has left solid ground and has tended to obscure the view for other facts in the area of lipids and other risk factors. The aim of this symposium is to present what is known and to discuss what is not yet known about HDL and coronary heart disease.

Figure 1 shows the lipid inputs from the gastrointestinal tract and the liver as dietary lipids or lipids of endogenous origin. A lipolytic cascade breaks down large triglyceride-rich lipoproteins to form smaller particles, which are then recognized by the liver or by peripheral cells because of certain apolipoproteins and cleared from the circulation. HDLs originate from the liver or from surplus surface materials of the large lipoproteins being broken down to accept cholesterol in the periphery and transport the steroid to the liver for degradation and excretion. It has been proposed that HDL_3, the protein-rich, lipid-poor HDL, is regenerated from HDL_2 by the action of lipolytic enzymes. Let us see how this scheme stands up in the presentations that follow.

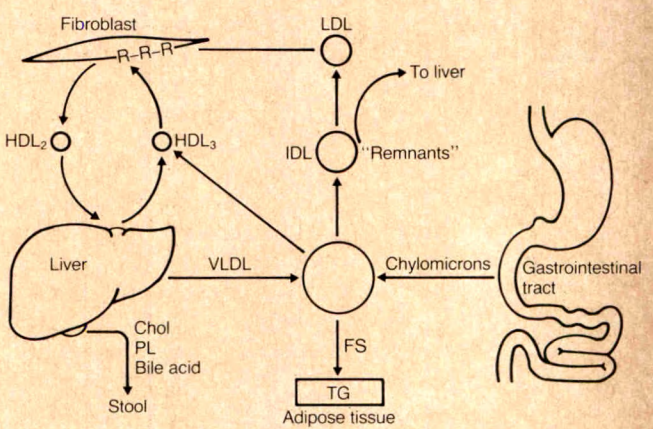

Figure 1. Lipoprotein metabolism in man. Chol = cholesterol; FS = free fatty acids; HDL = high-density lipoproteins; IDL = intermediate-density lipoproteins; LDL = low-density lipoproteins; PL = phospholipids; R-R-R = receptors; TG = triglycerides; VLDL = very low density lipoproteins.

High-Density Lipoproteins: Biochemical and Metabolic Factors

ANTONIO M. GOTTO, Jr., MD, DPhil

The high-density lipoproteins (HDL) are the smallest of the plasma lipoprotein families and are approximately one half lipid and one half protein by weight. The major lipid constituent of HDL is phosphatidylcholine, with sphingomyelin second, followed by cholesterol and cholesteryl ester. The principal protein constituent of HDL is apolipoprotein A-I. Nascent or newly secreted HDLs, appear to be secreted by the gut, lymph and liver. The nascent HDL are converted into the native particle by the action of lecithin:cholesterol acyltransferase. The transfer of a fatty acid moiety from phosphatidylcholine to cholesterol provides a core of cholesteryl ester for HDL and facilitates formation of a stable spherical particle. Another source of nascent HDL is hydrolysis of the triglyceride-rich lipoprotein particles, which results in the formulation of HDL_2. HDL_2 are larger than HDL_3 and contain more lipid-rich particles, whereas HDL_3 are relatively protein-rich, lipid-poor, and dense. The strong inverse relation between HDL and coronary artery disease is believed to be most closely related to the HDL_2 subfraction.

A brief background on our current knowledge of the metabolism and structure of the high-density lipoproteins (HDL) will be presented as a basis for understanding the subsequent presentations.

The HDL family consists of a group of particles that contain about one half protein and about one half lipid by weight (Fig. 1).[1] We believe that these particles contain lipids, cholesteryl ester, triglyceride and unesterified cholesterol and that these water-insoluble lipids are protected by a surface monolayer consisting of apoproteins and the polar head groups of phospholipids. This monolayer along the surface then tends to interact with the aqueous exterior and maintains the lipid in a soluble state as it is transferred from the blood (Fig. 1). The major phospholipid, or lipid, constituent of HDL is phosphatidylcholine or lecithin.

There are several sources of HDL (Fig. 2). Of the apoproteins or protein components of HDL, apo A-I and apo A-II may be synthesized in the gut and also in the liver. Under certain circumstances, apo E may be secreted by the liver and may form the basis for an HDL particle. Another source of HDL is hydrolysis of the triglyceride-rich lipoproteins, either the chylomicrons derived from the gut or the very low density lipoproteins (VLDL) derived from the liver. Therefore, there are at least 4 sources of the HDL that circulate in the blood. From the liver, a particle can be secreted that contains apo E, or possibly also apo A-I, which represents a nascent form of HDL. Similar particles containing apo A-I may be secreted by the gut. These particles are called nascent HDL because, when viewed by the electron microscope, they appear as a rouleau or stacked disk. They do not have a spherical structure. To convert the nascent HDL particle to an intact HDL particle, the HDL must be acted upon by the enzyme lecithin:cholesterol acyltransferase (LCAT), catalyzing the conversion of cholesterol to cholesteryl ester.

As the core of triglyceride is hydrolyzed during hydrolysis of triglyceride-rich particles, an excess of surface constituents remains consisting of cholesterol, phospholipid and apoproteins, which are transferred to HDL, increasing its mass. Lipoprotein lipase attacks VLDL, and the surface constituents are transferred to HDL_3, which in turn is converted to HDL_2.

This phenomenon was studied in an experiment in which VLDL was treated with lipoprotein lipase under in vitro conditions. HDL_3 was also present in the test tube in the mixture. At the end of the experiment, after the lipase had attacked the VLDL, the VLDL was converted to intermediate-density lipoproteins (IDL) and HDL_3 was converted to HDL_2. On this basis, a reciprocal relation would be expected between the concentration of HDL cholesterol and VLDL triglyceride. In fact, this is the case.[2] Similarly, there is a positive correlation between concentrations of HDL cholesterol and the activity of lipoprotein lipase.

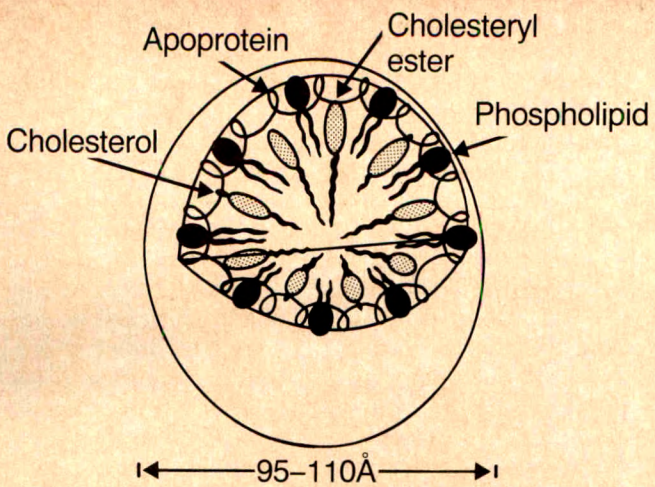

FIGURE 1. Schematic of a high-density lipoprotein particle. The protein is represented as having a helical structure and forming the outer 110 Å shell of the particle. The polar head groups of phospholipids are shown interacting with the helices of the protein. Cholesteryl esters are drawn such that the cholesterol moiety interacts with the fatty acyl chains of the phospholipids. Reprinted from Jackson et al.[1] with permission of the publisher.

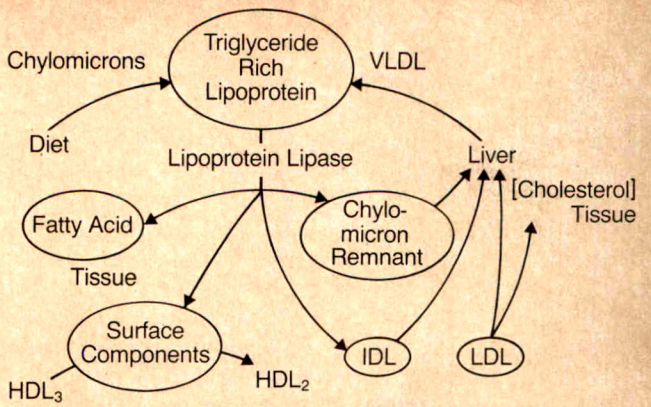

FIGURE 2. Schematic of lipoprotein metabolism. HDL = high-density lipoprotein; IDL = intermediate-density lipoprotein; LDL = low-density lipoprotein; VLDL = very low density lipoprotein.

It is interesting to compare differences in lipoprotein concentrations between males and females. The average concentration of VLDL is slightly higher in males. IDL is about the same. Males have a slightly higher average concentration of LDL and females a higher concentration of HDL, but by far the most striking difference is in HDL_2. Females have more than 3 times the concentration of HDL_2 than do males. Therefore, this difference in the ratio of HDL_2 to HDL_3, expressed in terms of concentration of HDL_2, is the most striking difference between lipoprotein concentrations in males and females.[3]

Table I shows apoprotein composition. The major protein component of HDL is apo A. By weight, apo A-I comprises about 46% of the total composition of HDL and apo A-II about 23%. There are 2 subfractions of HDL: HDL_2 and HDL_3. HDL_3 is relatively richer in apo A-II than is HDL_2, which has a relatively higher concentration of apo A-I. HDL also contains the apo C proteins C-I, C-II and C-III and apo D and apo E, which represent a very small proportion of HDL.

Three apoproteins form the apo A group of proteins: A-I, A-II and A-IV. A-IV appears to be made by the gut. In some species it is part of the HDL complex and in others it is found in the lipid-free state. Two apoproteins form the apo B group: B-100, the major protein of LDL made by the liver, and B-48, a minor constituent synthesized by the gut. The relative distribution of apoproteins within HDL is: A-I, 46%; A-II, 23%; C-I, 18%; C-II, 2%; C-III, 3%; D, 5%; and E, 1%. We do not have good data for A-IV. In all species studied to date, throughout evolution, apo A-I is the major apoprotein constituent of HDL.

There is a controversy about whether apo E–containing particles represent a separate, identifiable subclass within HDL. Some dietary experiments involving cholesterol feeding, particularly the feeding of egg yolks, show that concentrations of HDL and HDL_2 increase under such conditions, as does the concentration of apo E.[4] Whether this is an atherogenic or antiatherogenic effect is a matter of discussion.

Each of these apoproteins undoubtedly has 1 or more specific functions. They are involved first of all in the binding and solubilizing of lipids. Apo E is a recognition site for lipoproteins on the surface of particles. At least 1 of the isomorphic forms of apo E is recognized by receptors on the surface of hepatic cells, that is, the hepatocytes, and on the surface of other cells. Apo A-I and apo C-I are activators of LCAT, the major enzyme involved in the formation of cholesteryl ester in the blood. Apo C-II is the specific activator required for lipoprotein lipase. Some investigators have postulated that apo D may be involved in catalyzing the transfer of cholesteryl ester between HDL, LDL and VLDL,[5] but this hypothesis has been challenged.[6] There are other postulated roles, less well established and more controversial, for the other apoproteins. At least 3 major functions have been identified: the binding of lipids, service as a ligand or a recognition site for receptors on the surface of cells, and the regulation or modulation of enzymes involved in catalyzing the removal of lipoproteins from the circulation.

Within the apoproteins, there are lipid-binding sites, much as there are antigen-binding sites within antibodies. We call these regions amphipathic helices. For

HDL = high-density lipoproteins; IDL = intermediate-density lipoproteins; LDL = low-density lipoproteins; VLDL = very low density lipoproteins.

example, in an amphipathic helix in 1 of the apo C proteins, apo C-I, there is an outer polar-face such that the poles are water-soluble; soluble amino acids are oriented toward the exterior. On the opposite end of the alpha helix is a nonpolar or hydrophobic face that interacts with the water-insoluble lipid constituents of HDL.

We have identified the crucial features necessary for lipid binding, that is, the determinants for lipid binding by the apoproteins of HDL.[7] They consist of a critical link of amino acids. We believe 20 amino acids represent the critical link, that is, a bipolar amphipathic alpha helix with a nonpolar face and a hydrophilic face. This part of the peptide or apoprotein has a relatively high degree of hydrophobicity and the ability to form an alpha-helical structure on binding to lipids.

Our hypothetical model of a lipid-binding region is called a lipid-associating peptide (LAP). We believe this peptide has certain structural analogies to apo A-I. It can be represented as a wheel because when it binds lipids and forms an alpha-helical structure, one half of the helical wheel is oriented toward the exterior. The outer part of the wheel contains the water-soluble amino acids serine and glutamic acid. This part of the helical wheel would then be water-soluble and would tend to maintain the HDL and the lipid-associating particle in a soluble state with the exterior. On the opposite side of the helix, oriented toward the interior and interacting with the lipid, are the water-insoluble amino acids tyrosine, leucine, valine and tryptophan. We have synthesized a series of such peptides and tested them.

When we tested the lipid-associating peptide LAP-20, we found that it could solubilize and bind phospholipids and cholesterol in a way very similar to that of apo A-I, the major protein of HDL. We also tested the ability of the peptide to activate the enzyme LCAT, which has an absolute requirement for apo A-I or apo C-I. On testing LAP-20, we observed activation for apo A-I and also activation by LAP-20.

In a series of synthetic peptides, we compared the ability of the peptide to bind phospholipid with its ability to activate LCAT. In every example, unless the peptide formed the amphipathic helix and could bind phospholipids, it could not activate LCAT. Not all lipid-binding peptides could activate LCAT, indicating that there are structural determinants beyond the ability to bind phospholipids that are necessary for the peptide to be able to activate LCAT.[8]

In conclusion, the apoprotein constituents have specifically defined functions, one of them being the ability to bind and solubilize the lipids; otherwise, one would not have a lipoprotein. A second function is to serve as a recognition site so that the lipoproteins may be removed from the circulation and catabolized. A third function is to regulate or modulate the enzymes involved in the catabolism of lipoprotein. By devising a series of such synthetic peptides, we may be in a position to regulate or modulate the metabolism of HDL and develop a more reasonable rationale for the treatment and prevention of atherosclerosis.

Relation of High-Density Lipoproteins to Coronary Artery Disease

BARRY LEWIS, MD, PhD, FRCP, FRCPath

Low mean concentrations of high-density lipoprotein (HDL) cholesterol have long been recognized as a characteristic of patients with coronary heart disease, and the measurement of this fraction is a relatively strong discriminator between patients with coronary heart disease and those without. When subjects are ranked by the severity of coronary atherosclerosis determined angiographically, levels of HDL cholesterol, particularly of its HDL_2 subclass, are consistently lower in subjects with extensive disease than in those with minimal atheroma. HDL cholesterol is derived from a number of sources, mobilization from peripheral tissues being but one. Generally, longitudinal studies have confirmed that a low HDL cholesterol level is potently and independently predictive of a high risk of coronary heart disease, one exception being a study of subjects with hypercholesterolemia. Despite the strength of these epidemiologic associations, there is no evidence from experimental studies or clinical trials to establish that low HDL levels are causally important in atherogenesis.

An inverse relation between high-density lipoprotein (HDL) cholesterol levels and coronary heart disease was recognized 30 years ago.[1,2] This report reviews recent findings on this relation and lists 3 questions concerning its basis. The first is, how consistent is the inverse relation between HDL levels and coronary heart disease? Second, does this inverse relation reflect a causal interaction between this lipoprotein and atherogenesis? Third, how should such a relation influence current clinical practice?

In case-control data from a multicenter study in 4 European cities, mean HDL levels were shown to be consistently low in patients with ischemic heart disease. In all participating groups, HDL cholesterol was lower than that in matched controls, and in most or all centers, low-density (LDL) and very low density lipoprotein (VLDL) lipids were elevated (Table I). When the London data were segregated according to the patient's age, the low mean levels of HDL cholesterol were most pronounced in patients in whom ischemic heart disease developed earlier in life, and the trend did not reach statistical significance in older patients.[3]

To date, 5 longitudinal epidemiologic studies have been performed. The first of these was the study of more than 6,000 men in Tromso, Norway.[4,5] Lipoproteins were measured in persons in whom myocardial infarction subsequently developed and in twice as many matched controls. The HDL cholesterol concentration was substantially lower in those in whom ischemic heart disease developed than in the controls. Triglyceride levels were not significantly higher, whereas cholesterol levels were significantly higher in those in whom the disease developed (Table II).

In brief, similar observations were made in the Framingham study[6] and in the Israeli Heart Study (Table III).[7] However, in a prospective study in Gothenberg, Sweden, the HDL cholesterol level was not predictive of ischemic heart disease in a series of subjects with hypercholesterolemia.[8]

An informative form of case-control study was used by several groups of investigators in which patients were ranked according to the severity of the atheroma on coronary arteriograms, and the atheroma score was related to plasma lipoprotein levels.[9] A study by Jenkins et al[10] was especially attractive in that it used multivariate analysis to control for the effects of age, smoking and blood pressure. In patients with the severest atheroma, VLDL lipids were higher than in those with minimal coronary atherosclerosis; LDL cholesterol was higher and HDL cholesterol strikingly lower in those with the severest coronary artery disease (Table IV).

We used a similar design. In a consecutive series of more than 100 men who underwent coronary arteriography, we compared lipoprotein patterns in those in the lowest and highest quintiles and the middle 3 quintiles of a score of coronary atherosclerosis (Table V). HDL cholesterol was lowest in those with the severest disease. This effect was confined to the HDL_2 subclass. The mean HDL_2 cholesterol level was little more than half that of persons with minimal or no disease. There was a direct relation between LDL cholesterol level and the severity of coronary disease. The last 2 entries in Table V reflect indexes of the concentration of remnant particles in plasma, that is, of partly metabolized VLDL and chylomicrons. We found no difference in the ratio of cholesterol to triglyceride in lipoproteins with a density <1.019; this index did not discriminate between

se with gross disease and those with minimal disease. nen we classified the data differently and looked at distribution of atherosclerosis in persons in the hest and lowest quintiles of the distribution of the ncentration of HDL_2 cholesterol (Table VI), patients h the highest HDL_2 cholesterol had little more than third the mean coronary artery score of persons with lowest HDL_2 cholesterol levels.

Another source of information on the relation be-een HDL and atherosclerosis is found in the longi-linal investigation of Brooks et al.[11] Using arteriog-hy of the femoral artery tree and repeating the cedure 1 year later, they quantitated the severity of eroma and calculated the rate of progression of the ease between the 2 arteriograms. Progression was ersely related to HDL cholesterol and directly to L cholesterol (Table VII). In the intervention group l controls of a regression trial in man we found a di-t relation between mean LDL cholesterol and angi-aphic evidence of progression; although an inverse

relation between HDL and progression was seen it was weaker and not significant.

All of these studies show a connection between HDL and the atherogenic process; however, in some situations HDL does not show such a relation. In the collaborative study in which colleagues in Italy, Switzerland and Sweden and our group in London compared, by identical methods, the lipoprotein concentrations in normal persons of both sexes and different ages,[3] levels of both LDL and VLDL lipids were higher in the relatively high coronary heart disease areas in Sweden and in the United Kingdom than in Switzerland and in Italy. Therefore, an association exists between the mortality from ischemic heart disease in these 4 industrialized European cities and these lipoproteins. However, there were virtually no differences in HDL cholesterol. To the extent that interpopulation differences in coronary heart disease can be attributed to lipoprotein-mediated risk, such differences must be associated with LDL and perhaps with VLDL, but these interpopulation differences in coronary heart disease rates could not be attributed to differences in HDL cholesterol levels.

The answer of the second question concerning a causal relation between HDL and atherogenesis is unknown. As discussed by Gotto in this symposium, HDL enters plasma as a discoidal particle and is derived from both the small intestine and the liver. Its subsequent metabolism is considerably more complex, and for discussion we will isolate a few aspects. Under the influence of the enzyme lecithin-cholesterol acyltransferase (LCAT), the free cholesterol of nascent HDL is largely converted to cholesteryl ester, which comes to form the core of a spherical HDL particle.

TABLE VI Frequency of Coronary Artery Disease Related to Distribution of HDL_2 Cholesterol (n = 104)[9]

HDL cholesterol is derived not only from primary secretion by the liver and gut but also from other sources. Additional cholesterol transfers to HDL from extrahepatic cells, subsequently being converted by LCAT to cholesteryl ester. This cholesteryl ester may reach the liver, at least in part, by transfer through a specific transfer protein to triglyceride-bearing lipoproteins. These lipoproteins undergo further metabolism and are ultimately metabolized, at least in part, by the liver, returning their cholesterol to this organ. Therefore, HDL may play a role in initiating the uptake of cholesterol from peripheral cells rather than in transporting it to the liver for excretion in the bile.

Some HDL cholesterol, perhaps a considerable portion, is derived from triglyceride-rich lipoproteins (VLDL and chylomicrons) within the circulation, as a result of the action of lipoprotein lipase.

A third source of HDL cholesterol is the cholesterol derived from peripheral cells. The upshot of these processes is that HDL cholesterol is derived from multiple sources. Hence, an increase in the concentration plasma of HDL cholesterol does not establish that reverse cholesterol transport has been enhanced. Microsomal inducing agents, for example, increase HDL cholesterol probably by stimulating its hepatic secretion, and factors that activate lipoprotein lipase, such as certain drugs, probably increase HDL cholesterol by promoting transfer of cholesterol to HDL from VLDL and chylomicrons.

Some evidence suggests that high HDL cholesterol levels reflect an increase in reverse cholesterol transport. Miller et al[13] investigated the relation between levels of HDL cholesterol in plasma and the exchangeable pools of cholesterol in extravascular spaces. In this small study, remarkably significant inverse relations were found between the amount of HDL cholesterol in plasma and the amount of exchangeable cholesterol in the tissues, findings certainly compatible with a role of HDL in centripetal transport. Evidence also exists that HDL or particles that contain HDL apoproteins and phospholipids serve as acceptors of cholesterol when cells are incubated in their presence.

In persons who have inherited high levels of HDL, the exchangeable pools of cholesterol, especially the slowly exchanging pool, are far smaller than the pools in control subjects (Table VIII).[14] Coronary heart disease appears to be rare in such persons.

The relation between HDL metabolism and the metabolism of other lipoproteins is complex, and it is difficult to study variables in man that influence any single lipoprotein in isolation. For example, HDL levels are strongly correlated with the fractional catabolic rate of VLDL and with the activity of lipoprotein lipase in adipose tissue. The rate of production of VLDL is related, for obscure reasons, to the rate of synthesis of HDL. It is difficult in the intact organism to isolate the determinants in the consequences of changes in any 1 lipoprotein.

In summary, HDL does function as a circulating acceptor of cholesterol from peripheral cells. There is good evidence that HDL initiates the reverse transport of cholesterol from the periphery back to the liver. HDL or a subclass of HDL that contains apo E competes with LDL for receptor-mediated binding by cells, and thereby may reduce the uptake of LDL cholesterol by peripheral cells.

What are the implications of these findings for clinical practice? We have no evidence that interventions that change HDL concentration influence the risk of coronary heart disease. We do not have animal models; we do not have controlled trials analogous to those that have provided evidence for the beneficial effect of the reduction of total plasma cholesterol. A reasonable view is that in persons who have low HDL concentrations together with one or another form of hyperlipidemia, an optimal treatment should normalize all lipoprotein abnormalities.

High-Density Lipoproteins: Epidemiologic Profile and Risks of Coronary Artery Disease

WILLIAM B. KANNEL, MD, MPH

The lipid-atherogenesis connection has undergone an evolutionary metamorphosis from a focus initially on serum total cholesterol, subsequently on other lipids, then on the lipoproteins that transport them, and now on the distribution of cholesterol in the low-density lipoproteins (LDL), high-density lipoproteins (HDL) and very low density lipoproteins. It is now established that the relation of serum total cholesterol to coronary heart disease (CHD) derives chiefly from the atherogenic LDL component, and that level of HDL cholesterol is inversely related to risk. The protective effect of HDL is at least as strong as the atherogenic effect of LDL and is independent of lipids and other risk factors. Every change of 10 mg/dl in the HDL cholesterol level is associated with a 50% change in risk. At any level of serum total cholesterol, risk varies widely, depending on the LDL/HDL ratio. A serum total cholesterol/HDL ratio of 5.0 is associated with average risk; optimal ratios, around 3.5, correspond to half the standard risk. Further refinements in the lipid profile may be possible because there are several HDL and LDL subfractions with different atherogenic potential probably related to their apoprotein makeup. Only weak and inconsistent relationships of stroke and peripheral arterial disease to serum cholesterol and its lipoprotein fractions have been found, although there is the expected inverse relation to HDL cholesterol. An inverse relation of LDL level to stroke in women, and in men a possible excess mortality at very low serum cholesterol values attributed to colon cancer, have been reported.

This report evaluates high-density lipoprotein (HDL) from an epidemiologic standpoint and, in particular, focuses on its role as part of a lipid profile for predicting coronary disease and also as an ingredient of a cardiovascular risk profile. It is widely recognized that atherosclerosis is a multifactorial process, and blood lipids appear to play a central role. The concept of lipid atherogenesis has undergone an evolutionary metamorphosis from an initial focus on the serum total cholesterol, to a focus on the other lipids, and then to the lipoproteins that transport them. The 2 lipoproteins described by Gofman et al, the beta or low-density lipoproteins (LDL) and the pre-beta or very low density lipoproteins (VLDL), are clearly related to coronary incidence. There is also a metabolic metamorphosis of the lipid particles that occurs as VLDL is converted to LDL via transient IDL remnants. In this process there is a progressive enrichment with cholesterol, and it is now believed that the LDL fraction is the atherogenic component and that the HDL fraction may be involved in cholesterol removal from the tissues.

We have learned from Drs. Gotto and Lewis in this symposium that the frontiers of lipid atherosclerosis research now encompass the apoprotein makeup of these lipoproteins and the subfractions of HDL and LDL that may be more specifically atherogenic or protective. The recent evidence continues, however, to incriminate cholesterol, but it also indicates that we need to consider the distribution of the cholesterol in the lipoproteins and, furthermore, that we must take into account other factors that injure the endothelium, affect its permeability, influence the extent of smooth muscle proliferation and fibrosis, and affect platelet aggregation.

Epidemiologic studies have now firmly established that there is indeed a strong, prospective and independent association between the serum total cholesterol concentration and the occurrence of coronary heart disease (CHD).[1–3] This relationship has been demonstrated in both sexes. It has been demonstrated for all clinical manifestations of CHD. Over the usual range of values that the laboratory designates within normal limits, there is a 5-fold range of risk. We have identified no critical values where normal leaves off and abnormal begins. It would appear that the higher the level, the

HDL = high-density lipoprotein; LDL = low-density lipoprotein; VLDL = very low density lipoprotein.

greater the risk; the lower the level, the less the risk of coronary disease.

We now also know that the impact of cholesterol diminishes with advancing age; beyond age 65 years it is difficult to show any relation at all. We also recognize that cholesterol-related risk is markedly influenced by the coexistent risk factor levels, although at any level of other risk factors there is an independent relationship of CHD to serum total cholesterol value (Fig. 1). Thus, any level of cholesterol, high or low, has a very different significance, depending on the mix of the other risk factors. Furthermore, we now understand that it is also important to determine how this total cholesterol is distributed in the LDL and HDL fractions (Table I). It

is now clear that the positive relationship of the serum total cholesterol to CHD incidence derives mainly from the LDL cholesterol component. Thus, there is a strongly positive relationship between LDL cholesterol and the risk of coronary events (Table II). HDL cholesterol is inversely related to coronary incidence (Fig. 2), consistent with its purported role in removing cholesterol from the tissues. VLDL cholesterol and its triglyceride apparently make no independent contribution to risk, although it is related to coronary incidence taken alone in the univariate case. Even at high triglyceride values there is the expected inverse relationship of HDL to CHD incidence, while at low HDL values, there is no relationship of triglyceride to coronary incidence (Fig. 3).

On the basis of multivariate formal statistical analysis (as measured by the size of the multivariate coefficient), the protective effect of HDL appears to be greater than the atherogenic effect of LDL cholesterol. This has been shown so far only for the elderly Framingham cohort and needs to be corroborated in younger persons. Nevertheless, the evidence suggests that the HDL influence is at least as strong as the LDL influence. For every 10-mg increment in HDL, there is about a 50% change in coronary risk, a very powerful effect. Both the LDL and HDL effects are independent of each other,

† $p < 0.001$.

of all the other lipids, and of all the other major risk factors. Also, at any level of serum total cholesterol (or of LDL cholesterol), the CHD risk varies widely, depending on the ratio of LDL to HDL (or the ratio of total cholesterol to HDL). Both at low LDL values or high LDL values, risk is markedly influenced by the LDL/HDL ratio (Fig. 4).

Fortunately, a comparison of ratios made up of LDL to HDL with those made up of the more practical total cholesterol to HDL reveals risk gradients that are similar (Table III). Also, there is no particular benefit to making linear combinations of LDL and HDL compared with ratios based on likelihood ratio statistics. The ratio of the 2 lipoprotein-cholesterol fractions seems to provide as efficient a discrimination of cases from noncases (Table III). Hence, the total cholesterol/HDL ratio will efficiently identify patients who are at increased risk over the usual range of total cholesterol values. A ratio of about 5 is the average or standard risk. One of about 3.5 is about half the standard risk and can be considered optimal, whereas a ratio of 10 is double the standard risk, and a ratio of about 20 is 3 times the average risk. These are ratio numbers easy to remember.

HDL = high-density lipoprotein; LDL = low-density lipoprotein.

Adding triglyceride to the HDL and LDL lipid profile (Table IV) appears to do nothing to improve the efficiency of the estimation of risk. The combination of HDL, LDL and blood pressure exerts a very powerful influence on risk (Fig. 5). At any level of HDL, risk increases with LDL, and at any level of LDL and blood pressure, risk is markedly influenced by HDL. Consistent with the findings of Glueck in this symposium, persons with very high HDL values can tolerate a lot of variation in LDL and blood pressure with relative impunity (Fig. 5). Risk in persons with low HDL cholesterol levels is high and greatly influenced by coexistent LDL and blood pressure.

Some further refinements in lipid profiles may be forthcoming shortly. Several subfractions of HDL and LDL with different apoprotein makeups have the potential to further improve current lipid risk profiles. However, no prospective epidemiologic data exist to test this hypothesis.

Another feature that deserves further investigation is the relationship of these lipid profiles to other clinical atherosclerotic manifestations. There is sparse and inconsistent information on the relationship of lipid profiles to other atherosclerotic events such as stroke, cardiac failure or occlusive peripheral arterial disease. For HDL cholesterol, almost all the risk gradients are negative, consistent with a beneficial effect.

However, for LDL, there is a paradoxical effect of a strong inverse relationship to stroke incidence that deserves further investigation. Consistent with this, the Japanese have also reported an inverse relationship of stroke to total cholesterol. VLDL cholesterol does not seem to exert much of an influence of any sort on any of the other atherosclerotic events.

At the same time that the relationship of cholesterol to CHD mortality has been clarified, an interesting problem has arisen of an inverse relationship of serum total cholesterol to overall mortality and, in particular, to colon cancer mortality, that requires further investigation (Fig. 6 and 7). The findings are inconsistent and paradoxical, because they can be demonstrated only for men. Moreover, an examination of the relationship of diet to colon cancer indicates that a high-fat diet seems to predispose. This tends to discredit a causal relationship between low cholesterol and colon cancer.

Nevertheless, the aforementioned relationship to overall and noncardiovascular mortality raises the question of what an optimal cholesterol value is. Optimal values for prevention of coronary disease and atherosclerosis are probably 140 to 180 mg/dl. Those in the 180- to 200-mg/dl range also have a favorable overall mortality risk and a good health status. Total cholesterol values >200 mg/dl generally appear to be suboptimal in regard to cardiovascular health.

So far, the results of trials to reduce coronary risk by either drugs or diet have been rather unimpressive. This may well be because we have not started the investigation early enough and have not continued long enough; nor have we achieved a substantial enough reduction in the lipid values, and we may not have achieved an improvement in the LDL/HDL ratio. Fortunately, the measures advocated to prevent CHD—such as weight reduction, smoking abatement, exercise, correction of diabetes, and even moderate alcohol intake—also have a favorable effect on the HDL value.

Obviously, we need to learn more about the role of the lipid profile in promoting and predicting coronary disease and in evaluating the efficacy of treatment. However, recognizing the incompleteness of the state of knowledge is no excuse for failing to apply more effectively what is known.

Influence of Exercise on High-Density Lipoproteins

Lt. Col. GEORGE O. COWAN, MB, FRCP, RAMC

The effects of an intensive rehabilitation course on plasma high-density lipoprotein (HDL) levels were studied in 40 men, aged 29 to 56 years, with ischemic heart disease. The exercise consisted of aerobic activities that induced up to 80% of the maximal heart rate during three 20-minute periods daily for 5 days a week; the program lasted 3 weeks. Significant increases were found in the levels of HDL and HDL_2 and their ratios to total plasma cholesterol. These changes were similar in nonsmokers of cigarettes and in men who gave up or reduced smoking during the course and contrasted with negligible changes in those who continued to smoke.

This study reports the results of changes in high-density lipoprotein (HDL) cholesterol during a cardiac rehabilitation program. In the American army, 15% of the soldiers are grossly overweight, perhaps because the standard mess hall diet contains more than 4,000 kcal/day. At Fort Eustis, Virginia, 100 soldiers were ordered to restrict themselves to 1,500 kcal/day, and over 10 weeks they achieved an average weight loss of 20 pounds, with a decrease in blood pressure and triglyceride levels as well.

Great Britain still has one of the world's highest incidences of ischemic heart disease, and the risk gets worse the further north one goes. British army soldiers have the same overall incidence as the general male population of Britain. However, the differences uncovered through social class analysis of our figures by Lynch and Oelman[1] are perhaps surprising in that corporals and enlisted men have twice the standard mortality ratio from sudden death from myocardial infarction, and Sandhurst or West Point officers, for example, have one third of the standard mortality ratios. This finding presumably reflects many aspects of their very different lifestyles: their habits and upbringing in terms of diet, their habits and philosophy of exercise and leisure pursuits, the wide disparity in smoking habits and perhaps also hereditary and economic factors. In this study, bias for age distribution and geographic origin within the United Kingdom has been statistically removed.

From the Queen Elizabeth Military Hospital, Woolwich, London, England.

Address for reprints: Lt. Col. George O. Cowan, MB, Queen Elizabeth Military Hospital, Woolwich, London, England.

Methods

When the Queen Elizabeth Military Hospital in Woolwich, London, was opened in 1977, it was decided to devote a major effort to identifying and treating servicemen with coronary artery disease. Equipment for exercise electrocardiographic testing and thallium-201 myocardial perfusion scanning was installed, and the effort was coordinated by the establishment within the hospital of the joint services school of remedial gymnasts who, it was planned, would provide the expertise and motivation necessary to promote vigorous physical exercise in the rehabilitation of men who have suffered the severe physical and emotional trauma of myocardial infarction and who were well aware that this jeopardized their military career.

The cardiac rehabilitation course, therefore, had 3 aims: restoration of physical fitness, psychological repair and secondary prevention. All British army men are required to pass a test of fitness twice a year over a 3-mile (4.8-km) course in 26 to 30 minutes. We intended that subjects with ischemic heart disease would achieve the normal target for their age at the end of the course. Psychological repair comes through increased physical fitness and confidence and also through a very strong sense of group identity fostered by evening discussions. The third aim, secondary prevention, is unproved. However, we have now treated more than 300 men, and we know that the first 2 aims can be achieved safely. What I want to report is perhaps a hopeful aspect in relation to the aim of secondary prevention.

The cardiac rehabilitation course actually works in the following way. Men were assembled in groups of eight 6 to 8 weeks after myocardial infarction or coronary artery bypass surgery. Some men do 2 courses, 1 after the infarction and 1 after surgery. A few are included who have angina of effort only and have not had myocardial infarction. The group is supervised by 2 remedial gymnasts, and in many periods of the exercise, each patient is accompanied by a gymnast student. We specifically avoid having physicians present during

the exercise. The gymnasts are in control. The course lasts 3 weeks, with weekends off, making 15 days of progressive exercise.

On the first day a safe work load for each patient is determined by use of the Bruce treadmill protocol for exercise electrocardiographic testing and is based on, for the first week, 70% of the maximal heart rate; for the second week, 75%; and for the third week, 80%. We determined these figures empirically to start with, but in practice they are safe and effective. Beta-adrenergic blocking drugs are discontinued during the course. The exercise program is obviously progressive and is based on the plan of 3 periods each day of 20 minutes, building up to 40 minutes during which the target heart rates are achieved. The exercise program varies considerably according to the time of year and the taste of the group, but it is all aerobic exercise and contains a mix of jogging, short trot-sprints, calisthenics, swimming, cycling and brisk walking. Lectures and films on the etiology of ischemic heart disease and on diet and smoking are included.

Subjects are advised at the start of the course about the so-called prudent diet, low in animal fat and refined carbohydrates, and meals of this type are made available in the dining room, but the men are not compelled to avoid imprudent items. Alcohol is not available during the weekdays, of the course, but it is assumed that many men include it in their weekend relaxation. No significant changes were recorded in body weight or skinfold thickness during the course. The whole program is based on strict control of pulse rate, monitored by the subjects themselves and by the gymnasts.

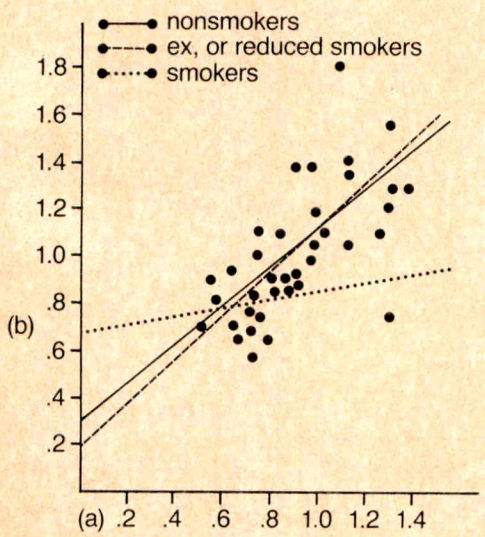

FIGURE 1. High-density lipoprotein levels (**a**) before treatment and (**b**) after treatment (in mmol/liter).

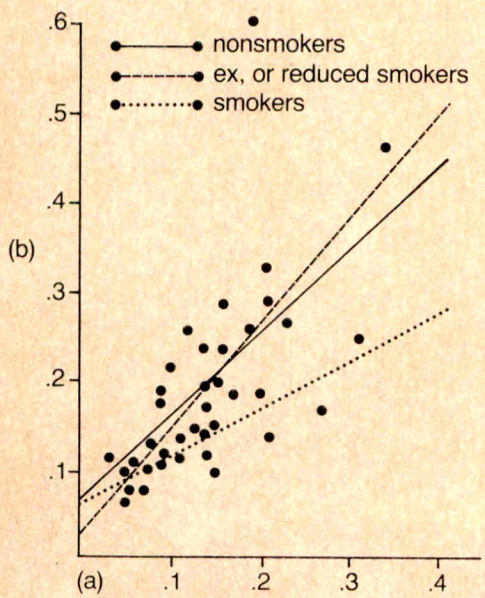

FIGURE 2. High-density lipoprotein$_2$ levels (**a**) before treatment and (**b**) after treatment (mmol/liter).

Results

The results of our study in 40 men aged 29 to 56 years (mean 40.6) compare fasting blood lipids taken on day 2 to those taken on day 17. HDL cholesterol increased from a mean of 0.87 to 0.95 mmol/liter (Fig. 1). HDL_2 increased from a mean of 0.14 to 0.19 mmol/liter (Fig. 2), and the ratios of HDL to cholesterol (Fig. 3) and HDL_2 to cholesterol (Fig. 4) also showed highly significant increases. The HDL_2 to total cholesterol mean increased from 0.026 to 0.039. Therefore, whichever way these data are analyzed statistically (Table I), these differences are all highly significant.

We wanted also to determine how cigarette smoking affected the results. Of the 40 men in the group, 19 did not smoke, 15 either stopped or reduced smoking markedly during the course and 6 continued to smoke as before. The separate regression lines show that nonsmokers and exsmokers had a significant increase in HDL and that smokers had virtually no change at all (Fig. 5). For HDL_2, the same applies. There was some increase in HDL_2 in the smokers, but it was not nearly as great as that in the other groups (Fig. 6). Again, statistical analysis shows that only those who continued

to smoke had no significant change, and the differences between the 3 subgroups are all highly significant (Table II).

It is well established that in the general asymptomatic male population of developed countries, plasma HDL is highest in the most physically active. It is equally well established that HDL and HDL_2 levels correlate strongly with the incidence, severity and mortality from coronary artery disease. Huttunen et al[2] studied 18 male coronary patients exercised to 70% of maximal oxygen uptake 3 times a week for 20 to 40 minutes over a 3-month period and found a 15% increase in total HDL, from a mean of 1.02 to 1.18 mmol. Streja and Mymin,[3] in a cardiac rehabilitation program, studied 32 sedentary men with coronary artery disease over a 13-week period, exercising them by jogging 2.8 km 3 times a week, and found only very slight increases in HDL.

Our study of 40 men with coronary artery disease shows that they may be exercised vigorously. For instance, on the Thursday of the third week, it is common for men on the course to cover 12 miles on foot with a mixture of running and walking, to swim 30 lengths of

a 33-meter pool and to play a couple of games of volleyball as well, which is very hard exercise. This amount has been achieved safely and within a few weeks of myocardial infarction or coronary artery surgery. Moreover, we have shown that this short, intensive course of exercise produces highly significant changes in plasma HDL, which may be prognostically favorable if maintained (Table III).

Continued cigarette smoking, however, virtually negates these changes. A recent study from Lund, Sweden, of HDL levels after smoking was stopped, performed by Stubbe et al,[4] showed a 29% increase in 2 weeks, but it was notable in our study that HDL changes were equally significant in the nonsmokers and in those who quit.

Acknowledgment: I would like to thank many members of the staff of my own hospital for their assistance and particularly Professor Barry Lewis and his staff at St. Thomas' Hospital for their help with this work.

Influence of Diet on High-Density Lipoproteins

GÜNTER SCHLIERF, MD, LENORE ARAB, MD, and PETER OSTER, MD

Evidence of a relation between diet and high-density lipoprotein (HDL) levels in humans comes from numerous cross-sectional and experimental studies. Evaluation of data from cross-sectional nutrition and health surveys sometimes yields different results for men and women but usually demonstrates positive correlations of HDL cholesterol levels with total energy intake, alcohol consumption, dietary cholesterol and total and animal fat, and negative correlations of HDL with dietary carbohydrates (simple sugars) and, in some instances, plant fats. Short-term dietary manipulation produced confirmatory evidence of a causal relation between diet and HDL with regard to several of these factors; however, there are few long-term data.

The underlying mechanisms as well as the relation of HDL manipulation to cardiovascular health are still to be defined, particularly because the functions and fates of the HDL molecule may vary according to its composition and turnover, which are not reflected by the HDL cholesterol concentration. Furthermore, some relations between diet and HDL may only be the result of other metabolic consequences of dietary change, for instance, triglyceride metabolism and other lipoproteins.

Although there is consistent evidence that a high HDL cholesterol level is indicative of a low risk of coronary heart disease in industrialized populations, evidence is inconclusive that manipulation of HDL leads to an alteration of risk.

Because plasma lipoproteins are either directly or indirectly derived from the food we eat, it is not surprising that diet affects lipoprotein concentrations in a powerful way. Epidemiologic studies and controlled experiments support the theory that atherogenic lipoprotein patterns and concentrations in most cases have environmental origin and, thus, essentially are amenable to normalization. High-density lipoprotein (HDL) cholesterol levels differ from person to person, and the plasma concentration can be induced to increase or decrease by factors that we can manipulate. Diet is prominent among these factors. Although this brief report reviews some dietary effects on HDL, there is little unequivocal evidence on this topic. Different studies have given different answers owing to different methods and, possibly, different responsiveness of persons. Duration of experiments may also be a crucial factor, and adaptation to the situation may occur.

Most people in discussing or studying HDL actually discuss and study HDL cholesterol, which is but 1 constituent of HDL. It may not always reflect the actual concentration of these lipoproteins, which have a density >1.063, particularly when the ratio of HDL subclasses is altered or when dietary changes lead to compositional changes of HDL particles. Even when dietary effects on HDL have been established, such as the occurrence of a particular HDL on high-cholesterol diets as described by Mahley,[1] conclusions about the long-term health consequences of such changes remain tentative. With these precautions, the following brief report is given.

Cross-sectional studies: Data from cross-sectional studies can be found in our survey of 20- to 40-year-old Heidelberg men and women.[2] We established dietary habits and measured lipoproteins. Significant positive correlations with HDL cholesterol were found for dietary energy, probably mediated by energy expenditure, and for alcohol (Fig. 1). An inverse (negative) relation was noted for sugar intake (Fig. 2) and plant fat intake (Table I). In addition, other studies of similar design found positive correlations with total and animal fat as well as with dietary cholesterol.

Interpretation of such cross-sectional correlation data requires 2 considerations. The first is that correlations do not establish causality, and the second is that noncorrelations do not establish ineffectiveness of the respective dietary factor.

Complementary evidence comes from the study of populations with different dietary habits, for example,

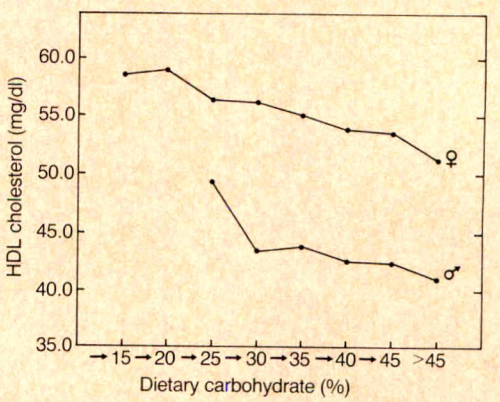

FIGURE 2. High-density lipoprotein (HDL) cholesterol and relative amount of dietary carbohydrate (Heidelberg study).

vegetarians.[3] The vegetarian diet is low in total and animal fat, cholesterol and sugar and is high in carbohydrates, fiber and plant fat. The lipoprotein patterns are characterized by substantially lower total and low-density lipoprotein (LDL) cholesterol concentrations, but also lower HDL cholesterol concentrations (Table II). Data on cardiovascular health in these people support the theory that HDL must be evaluated in relation to LDL and that low HDL may lose its role as a risk indicator if LDL is also low.

Controlled dietary experiments: Controlled dietary experiments are a more direct approach to the study of diet-HDL relations. Data from our metabolic ward[4] on the effect of a prudent diet in familial hypercholesterolemia and in endogenous hypertriglyceridemia show that a fat-modified, low-cholesterol diet given for 3 weeks, while appreciably affecting LDL and very low density lipoprotein (VLDL) levels, has no effect on HDL cholesterol concentrations. Others, using similar diets, even found an acute decrease in HDL cholesterol, with a lipid-lowering prudent diet.[5] Such an acute decrease in HDL cholesterol was shown in an experiment in which subjects were switched from a high-fat, low-carbohydrate diet to a low-fat, high-carbohydrate diet.[6] This marked decrease in HDL cholesterol was seen concomitant with changes in other lipoproteins (Table

III). Because such a considerable decrease in HDL cholesterol is not observed in populations on habitual high-carbohydrate diets, we speculate that concomitant with the reversal of carbohydrate-induced hypertriglyceridemia, HDL cholesterol would increase upon continuation of such diets for months or years.

Confirmatory evidence for this theory of a difference in short- and long-term dietary effects is supplied by data from the Oslo study.[7] In this long-term experiment on the effects of a prudent diet, along with the predicted changes in total cholesterol and LDL cholesterol, there was an increase in HDL cholesterol (Table IV).

An interesting hypothesis put forward by Knuiman and West[8] is that high HDL cholesterol is a negative risk factor or indicator in populations on high-fat diets because it reflects the ability to handle dietary fats. Low HDL found in many populations or groups on low-fat diets would lose its role as an indicator of risk because the challenge of fat loads is lacking. Thus, only on a high-fat diet, low HDL cholesterol indicates a high risk, and higher HDL cholesterol levels, lower risks.

I would like to have discussed experiments on the effect of meat versus fish protein, of different dietary fibers, of vitamin and mineral supplementation, of total fasting or of hyperalimentation, which have all been studied since HDL became "famous." Because space does not permit, I will summarize. Dietary factors do influence HDL. Acute effects probably differ from long-term effects. In most studies, a prudent diet, owing to its dominant influences on LDL, favorably affects LDL:HDL ratios. If LDL and HDL are low on a low-fat diet, this finding appears also to be consonant with a low cardiovascular risk. If HDL levels are low on a high-fat diet, do worry. Do not worry about HDL cholesterol on a low-fat diet. Much work remains to be done to answer the key question: whether manipulating HDL by any means leads to alteration of risk of coronary heart disease.

Discussion—High-Density Lipoproteins: Epidemiology and Physiologic Influences

GÜNTER SCHLIERF, MD, Moderator

Dr. Kostner (Graz, Austria): It has been pointed out in almost every report presented that HDL is a composition of several classes or families. It has also been shown that by measuring HDL_2, one can possibly discriminate better than by measuring total HDL. My question to Tony Gotto or Barry Lewis, therefore, is, can we recommend any fraction within HDL that may discriminate better than total HDL?

Dr. Gotto (Houston, Texas): If it is possible in a particular clinical laboratory, I would prefer having a measurement of HDL_2. If that's not feasible, then I would take a total measurement of HDL cholesterol.

Dr. Lewis (London, England): Yes, I concur with that. The options, then, in doing so are to use a precipitation method or ultracentrifugation. The 2 correlate reasonably closely, although the results are not identical. We have found very satisfactory the use of a small air-driven ultracentrifuge made by Beckman that produces HDL_2 results within about 3 hours.

Dr. Schlierf: The specific part of the question was whether measurement of one of the apolipoproteins could replace the more cumbersome subfractionation of HDL. Would you say a word on this, Dr. Gotto?

Dr. Gotto: I am not sure I can answer that question at the moment. The measurement of apoproteins and apoprotein subfractions is coming into its own. At present, this is still experimental. Apo A-I will correlate more closely with HDL_2 than with HDL_3, but the difficulty in making the correlations with the apoprotein concentrations is that on a very low cholesterol diet the proportion of apoprotein in the lipoprotein family increases. This is true of all lipoprotein families, whether LDL or HDL. We do not know at the moment how to interpret these findings. What is the significance of the finding that the apo A-I increases out of proportion to the amounts of cholesterol? Questions have also been raised about whether apo B itself is a risk factor. Until we have epidemiologic information of the kind Dr. Kannel was discussing, I think that this still has to remain in the level of experimental work.

Dr. Schlierf: Thank you. The next question please.

Dr. Förster (Halle, German Democratic Republic): I would like to mention a point of view not discussed in these reports. For many years we have been trying to assess the influence of lipoproteins on prostacyclin biosynthesis. Many investigators believe that in atherogenesis the antiaggregatory effect of prostacyclin may be important, and we could show that HDL has an increasing effect on the prostacyclin synthesis activity, whereas LDL has a decreasing effect. These differences seem to be specific and are dependent on sex and also on age. There were differences in premenopausal and postmenopausal women. We believe this new point of view should be incorporated in the discussion of the pathogenesis of atherosclerosis.

Dr. Schlierf: Thank you for this interesting and timely contribution. Dr. Smith, your question please.

Dr. Smith (Aberdeen, Scotland): I was fascinated by Colonel Cowan's statistics on a 6-fold difference in coronary risk between the enlisted men and the Sandhurst officers. I wonder if you have any lipoprotein data on these 2 groups?

Dr. Cowan (London, England): Unfortunately not. In our organization we are always reluctant to bleed men in large numbers. Although obviously it would be a very interesting study, it has not yet been done.

Dr. Schlierf: The next question is from Dr. Kumerow.

Dr. Kumerow (Chicago, Illinois): Dr. Gotto demonstrated the hydrophobic and hydrophilic effects on the HDL molecules when exposed to egg yolk. If the egg white had been included, would it have changed the ratio of the hydrophobic to the hydrophilic apoprotein?

Dr. Gotto: A low-cholesterol diet would increase the total proportion of apoproteins in HDL. It would also relatively decrease HDL_2 more than it would HDL_3. I have not thought about this question specifically, but I would predict that it would cause a relatively greater decrease in apo A-I, the more hydrophobic of the apoproteins.

Dr. Schlierf: Thank you. The last question.

Dr. Banta (Australia): I would like to comment on the role of HDL in reverse cholesterol transport. Much has been said about how this happens. If it does happen, it must involve an esterification of cholesterol by LCAT, but then there are a number of problems. Firstly, patients with high concentrations of HDL do not esterify more cholesterol; if anything, their rate of cholesterol esterification is lower. Therefore, it is difficult to regard the role of HDL in protection as being that of reverse cholesterol transport. The second point is that if you make very simple arithmetic calculations on the amount of HDL being removed from the plasma, even if 100% of the HDL in human plasma were taken up by the liver, it accounts for the removal of only about 5% of the cholesterol ester formed. LDL, on the other hand, can account for about 80 to 90% of the cholesterol being removed from the plasma. We have to consider whether the correlations with HDL are reflections of other things. Possibly 1 thing we are currently not measuring in overnight fasted blood samples relates to the concept of the 24-hour integrated chylomicron membrane concentration. I do not know how we could measure it.

Influence of Bezafibrate, Fenofibrate, Nicotinic Acid and Etofibrate on Plasma High-Density Lipoprotein Levels

RODOLFO PAOLETTI, MD, GUIDO FRANCESCHINI, PhD, and
CESARE R. SIRTORI, MD, PhD

Increased levels of plasma high-density lipoprotein (HDL) cholesterol have been described after exposure to different dietary (such as ethanol) and environmental (such as chlorinated pesticides) factors as well as intense physical training. Several lipid-lowering drugs have also been shown to elevate HDL cholesterol. These findings are of particular interest, because adult levels of the putatively protective lipoprotein fraction appear not to be regulated by genetic factors.

Four hypolipidemic drugs are herein considered, all of which reportedly elevate HDL cholesterolemia. Two of them, bezafibrate and fenofibrate, belong to the class of "fibrate" derivatives; nicotinic acid (NA) and etofibrate (E) show some similarities, E being the chemical association between nicotinic acid and clofibrate. In most studies, bezafibrate (B), with a very short half-life (2.1 hours), has induced an HDL cholesterol elevation of about 20%, both in types II and IV hyperlipidemic patients; it is controversial whether HDL_2 rather than HDL_3 levels are elevated by B. Fenofibrate (F) shows prolonged plasma half-life in man (>21 hours) and markedly increases HDL cholesterol levels, particularly in type IV patients; data are less homogeneous in type IIA and IIB cohorts. It appears that F may increase apoprotein C-II levels in very low density lipoproteins, possibly an index of stimulated lipoprotein lipase activity. Both B and F may behave as "catabolic agents," stimulating the breakdown of triglyceride-rich lipoproteins and the transfer of surface components (free cholesterol) to HDL. A different case may be that of NA, which prevents the decrease of HDL cholesterol induced by carbohydrate-rich diets in volunteers. NA reduces the catabolism of HDL and markedly increases (300% or more) the HDL_2/HDL_3 ratio in both volunteers and type IV patients, but not in type IIB patients. Whether, in addition to a "sparing" action on HDL, NA may also increase HDL levels by stimulating lipoprotein lipase activity is being disrupted. Finally, E may increase HDL cholesterol by 10% or more while exerting significant hypocholesterolemic activity. This compound is of interest because it may stimulate the release of prostacyclin from the arterial wall; prostacyclin may be derived from HDL phospholipids, unusually rich in arachidonic acid. This observation may offer another clue to the understanding of the mode of arterial protection exerted by HDL.

The association between elevated high-density lipoprotein (HDL) cholesterol levels and reduced prevalence of ischemic events in the heart,[1] brain[2] and possibly other vascular areas[3] seems well established. However, aside from the epidemiologic implications of this finding, few if any data support the potential benefit of increasing HDL cholesterolemia. Indeed, dietary treatments for hyperlipidemia, particularly the use of diets rich in polyunsaturated fatty acids, seem to reduce rather than increase HDL cholesterol levels.[4] Currently, only ethanol, among dietary components, has been associated with increased HDL cholesterol levels.[5]

Despite an apparent inclination toward a prevalent role of genetic factors in regulating HDL cholesterolemia, still the role of "environmental" agents seems essential. In fact, no genetic link could be detected between the HDL cholesterolemia of parents and children,[6] indicating that adult levels of this presumably protective lipoprotein fraction are markedly regulated by other factors. Among these, hormones undoubtedly play a role,[7] as certainly also do ethanol consumption,[5] physical exercise[8] and environmental pollutants stimulating HDL production.[9] However, it is still controversial which of the 2 subfractions of HDL, that is, HDL_2 and HDL_3 (see other reports in this symposium), is specifically increased by each environmental, dietary and drug factor. This controversy stems in part from the uncertain definition of which of the 2 HDL subfractions exerts the "protective" role in atherogenesis.[10]

Because adult HDL cholesterol levels are a product of numerous external factors, a distinct possibility exists that drug treatment, if positively affecting HDL cholesterolemia, might also provide a useful therapeutic mode of prevention of arterial degenerative disease. In

IGURE 1. Structural formulas of bezafibrate, fenofibrate (procetofen), cotinic acid, and etofibrate.

his brief review, 4 different drugs, all reportedly ele-ating levels of HDL cholesterol, are examined in terms f both their general pharmacologic properties and their ode of eliciting elevated levels of this possibly pro-ective lipoprotein.

Pharmacologic Characterization of the Compounds

Two agents under evaluation belong to the general oup of aryloxyacids, the prototype of which is clofi-rate.[11] Nicotinic acid seems to share some of the roperties of the "fibrate" derivatives, such as the ac-vation of lipoprotein lipase,[12,13] but also shows prop-ties of its own, particularly reduced adipose tissue polysis.[14] Finally, etofibrate shares some of the prop-ties of both "fibrates" and nicotinic acid, being a olecular association of the 2 compounds (Fig. 1); ap-arently, etofibrate may display some of the beneficial properties of the components, but with a lower incidence of side effects, compared with nicotinic acid.

Bezafibrate: The general pharmacology of this agent is quite similar to that of clofibrate; that is, it induces particularly both a marked reduction in plasma cholesterol levels[15] and a significant liver weight gain[16] in rodents on hyperlipidemic regimens. Bezafibrate is 3 to 4 times more potent than clofibrate in standard tests of hyperlipidemia. The liver weight gain in rodents after bezafibrate results, as with clofibrate, from the proliferation of peroxisomes.[17]

Kinetic studies with bezafibrate in man, however, show considerable differences from clofibrate. The apparent half-life of bezafibrate in serum is, in fact, only about 2.1 hours,[18] compared with 10 to 30 hours for chlorphenoxyisobutyric acid, the active metabolite of clofibrate. The relatively rapid absorption and elimination, with a very high plasma clearance (around 100 ml/min), indicate favorable pharmacokinetic properties. The short half-life and efficient clearance (half renal and half metabolic) make cumulation highly unlikely.

Fenofibrate: Fenofibrate displays very effective cholesterol- and triglyceride-lowering activities in animal models, being at least 10 times more potent than clofibrate.[19] Similarly to bezafibrate, fenofibrate induces peroxisome proliferation and liver weight gain in rodents.[17]

Differently from bezafibrate, fenofibrate has a prolonged plasma half-life in man. The drug is only moderately well absorbed in the unchanged form (about 30%), being eliminated as free acid. Terminal plasma half-life is in excess of 21 hours,[20] apparently unchanged after long-term treatment and not influenced by concomitant intake of anion exchange resins.[21] Differently from bezafibrate, fenofibrate may therefore not require repeated administration during the day.

Nicotinic acid: The mode of the lipid-lowering action of nicotinic acid has been the subject of many reports, mainly indicating the powerful antilipolytic activity of the agent,[14] which is not reviewed herein.

The metabolic fate of nicotinic acid is complex, leading to conjugative products (methyl or glycine

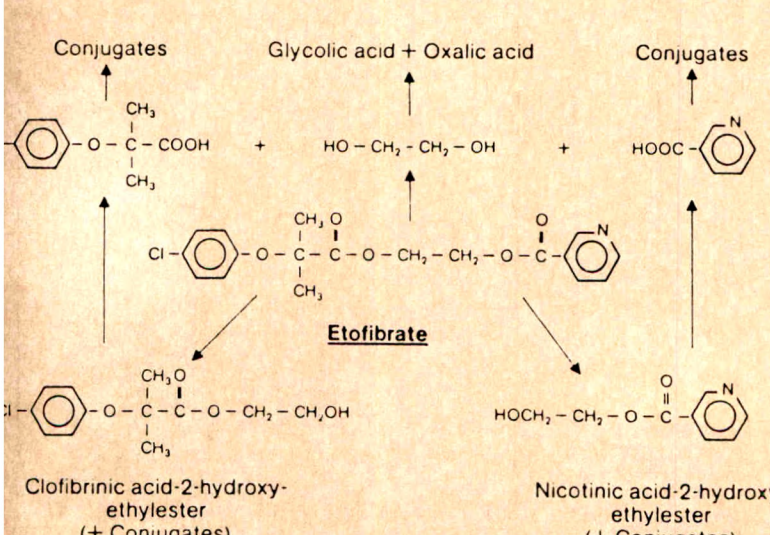

FIGURE 2. Metabolic breakdown pattern and major catabolic products of etofibrate in man.

conjugates) and to other oxidated metabolites.[22] In general, the compound undergoes extensive first-pass handling, with the formation of nicotinuric acid taking place within the first 2 hours of the dose, followed by a slower metabolic pathway (essentially with methylated metabolites) proceeding for more than 12 hours.[23] With larger doses (exceeding several grams per day), metabolism is considerably altered, with more than 80% of the administered drug appearing in an unchanged form in the urine.

The major side effect of nicotinic acid administration, dilation of superficial vessels, with a characteristic "flush," appears in the first 10 to 20 minutes after administration and is closely correlated with the increase in nicotinic acid levels in plasma.[24] With repeated doses a gradual tolerance develops, so that flushing tends to become less severe, although it usually continues to some degree after each dose. Of the many nicotinic acid derivatives in clinical use, nicotinyl alcohol, D-glucytol hexanicotinate (sorbinicate)[25] and pentaerythritol tetranicotinate (niceritrol)[26] are the most widely used, being effective at lower doses and with less severe side effects. More recently, the pyridine N-oxide analog of nicotinic acid (acipimox) has shown an impressive pharmacologic profile[27] and a valid lipid-lowering activity in man.[28]

Etofibrate: Etofibrate is the condensation product of clofibrate and nicotinic acid, giving rise to a variety of metabolic derivatives (Fig. 2). The fate of the 2 major metabolites, clofibrate and nicotinic acid, is similar to that of the 2 parent drugs. Etofibrate apparently has a reduced acute toxicity compared with clofibrate and clofibric acid, and is well tolerated on prolonged administration. In rodents, etofibrate shows more marked cholesterol-lowering activity than clofibrate.[29] This agent produces a lower incidence of side effects in man compared with nicotinic acid.[30]

Potential Mechanisms of the HDL Increase Induced by Drugs

Plasma HDL levels, as pointed out, are influenced by a variety of factors. HDLs are secreted from the liver and intestine. The quantitative analysis as well as the chemical composition of particles secreted by the 2 tissues are the object of other presentations in this symposium. Catabolism of HDL occurs mainly in the liver and may be influenced by dietary fat and carbohydrate intake.

Two general mechanisms seem to be involved in determining the final levels of HDL and particularly of HDL cholesterolemia: (1) changes in HDL metabolism after alterations in the synthetic or catabolic rates of HDL and their polypeptides, or both, and (2) alterations in lipoprotein interconversion through control of the key enzymes involved in the process.

High-carbohydrate diets reduce HDL cholesterol levels in association with an increased turnover of HDL particles.[31] Moreover, lipid-lowering, fat-controlled diets may reduce HDL cholesterol and apoprotein A-I levels, possibly by decreasing the intestinal synthesis of apo A-I–containing lipoproteins.[32] In contrast, diets high in cholesterol and saturated fat increase both HDL cholesterol and plasma apo A-I levels,[33] also inducing the formation of apo E–containing lipoprotein particles in the HDL density range.[34]

An increase in HDL levels may also occur after treatment with agents that increase liver protein synthesis, such as enzyme inducers. Such findings have been reported with antiepileptic agents in man;[35] exposure of experimental animals or man to TCDD or to chlorinated insecticides also increases HDL cholesterol levels.[9,36]

A possible major mode of action of drugs affecting HDL cholesterol levels may be related to changes in the interconversion of lipoprotein particles in the blood. During catabolism of very low density lipoproteins (VLDL), surface material, such as apolipoproteins and cholesterol, is transferred to the HDL pool.[37] An increase in VLDL turnover is produced by a variety of factors stimulating the activity of the lipoprotein lipase (LPL) enzyme. Among environmental factors, such a mechanism has been postulated for physical exercise and for alcohol consumption. Increased HDL cholesterolemia and apo A-I levels are detected in physically well-trained men and may be induced by appropriate exercise programs.[8] An increase of LPL activity may be detected in both adipose tissue and skeletal muscle during training.[38] Chronic consumption of ethanol has also been associated with increased LPL activity and elevated HDL cholesterol levels.[39]

Different mechanisms have been postulated for the modulation of HDL levels by sex hormones. Women have higher levels of total HDL and HDL_2 but lower HDL_3 concentrations than men.[7] The administration of estrogens to persons of either sex increases HDL levels, which conversely are reduced by androgenic and progestational hormones.[40] Changes in HDL cholesterol levels during the use of contraceptive preparations are generally related to the estrogenic or antiestrogenic activity of the progestogen in the pill.[41] Interesting effects may be displayed by sex hormones on hepatic lipase, an enzyme involved in the catabolism of HDL particles. Estrogens, in fact, suppress hepatic lipase activity and induce an increase in HDL; androgens stimulate this enzyme activity, decreasing HDL levels.[42]

An increase in HDL concentrations should be a definite aim in the treatment of patients with hyperlipidemia. The most commonly used hypolipidemic agents generally produce such an effect. A direct influence on HDL metabolism has also been suggested for cholestyramine, which may increase the HDL_2/HDL_3 ratio and apo A-I levels by increasing the synthetic rate of apo A-I.[43] The effect of the "fibrate" derivatives seems to be related to increased LPL activity, best noted in subjects with depressed VLDL catabolism. Finally, nicotinic acid and derivatives may act by the same mechanism as the "fibrates" and may also inhibit the catabolism of HDL.

Bezafibrate: Bezafibrate has shown somewhat better plasma cholesterol- and triglyceride-lowering activity compared with the reference compound.[44] In patients with hypertriglyceridemia, bezafibrate decreases plasma total and VLDL-associated triglycerides by about

45%.[45] Several investigators have reported increases in HDL cholesterol levels of about 20%.[45,46] An increase in cholesterol and apo A-I in the HDL_2 subfraction has been reported[47] (Fig. 3); however, recent findings indicative of a reduced ratio between plasma apo A-I and A-II levels during bezafibrate treatment suggest a probable increase in HDL_3.[45,48] The significance of these discrepancies is unclear. Bezafibrate improves plasma postheparin LPL activity and intravenous fat tolerance;[45] this possible mechanism of the hypotriglyceridemic effect of bezafibrate is consistent with an increase in the HDL_2 subfraction as a product of the catabolism of triglyceride-rich lipoproteins.[37]

In patients with hypercholesterolemia, bezafibrate increases HDL-associated cholesterol, apo A-I and apo A-II; these HDL components are still elevated 6 weeks after discontinuation of therapy,[49] thus indicating a prolonged effect of the agent. Increased HDL cholesterol levels have also been reported in hyperlipidemic, non–insulin-dependent patients with diabetes; in the same patients, lecithin cholesterol acyl transferase activity does not change, suggesting a lack of effect of bezafibrate on the interconversion of HDL subspecies.[48]

Increased levels of HDL cholesterol after bezafibrate treatment have not been noted consistently by all investigators.[50] However, in all patients with hyperlipoproteinemia treated with the compound, improvements in the HDL/LDL and the apo A-I/apo bezafibrate ratios have always been observed. These findings indicate that bezafibrate treatment may effectively reduce lipoprotein-linked atherogenicity.

Fenofibrate: Fenofibrate, a clofibrate derivative, shows a powerful hypolipidemic activity at relatively small daily doses (300 to 400 mg). It markedly depresses total plasma cholesterol and triglyceride levels in both patients with type II and those with type IV hyperlipidemia.[51] A recent comparative study with cholestyramine in type II patients indicates that fenofibrate is slightly more effective than the anion exchange resin.[52] In all studies, fenofibrate treatment has led to a more favorable HDL/LDL ratio, mediated through a reduction in the atherogenic components and in most cases by increase in HDL levels. In some studies, however, a reduction in HDL cholesterol was reported in patients with type IIA disease.[53]

After the start of fenofibrate treatment, a rapid increase in plasma apo A-I levels may be detected (particularly in patients with type IIB disease).[51] The absence of a concomitant increase in HDL cholesterol suggests a quantitatively different effect of fenofibrate on the 2 components of HDL, that is, cholesterol and apoproteins. However, HDL cholesterol increase in type IV patients is constant and reproducible in all studies (Fig. 4).

The mechanism of the hypolipidemic effect of fenofibrate is still incompletely clarified. An increase in the apo C-II content and the apo C-II/C-III-1 ratio in VLDL has been described by our group (Fig. 5). This finding is consistent with the observed increase in LPL activity after fenofibrate treatment.[54] Therefore, fenofibrate appears to belong to a group of drugs that exert mainly a catabolic effect on triglyceride-rich lipoproteins. This effect may result in increased HDL cholesterol levels, particularly in patients with hypertriglyceridemia.

Nicotinic acid: Treatment with large doses of nicotinic acid is generally associated with a marked reduction in both plasma cholesterol and triglyceride levels of about 15 to 20% and 45 to 50%, respectively. More recently, increases in HDL cholesterol have been reported by several investigators[55] and studies have been carried out in both normolipidemic volunteers and pa-

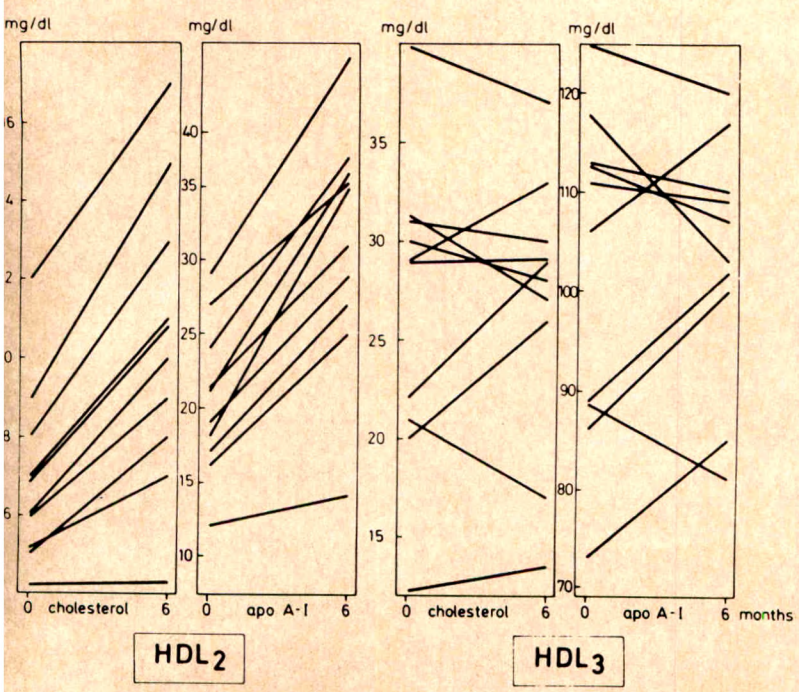

FIGURE 3. Increased concentration of cholesterol and apoprotein A-I in the HDL_2 subfraction after long-term treatment with bezafibrate. HDL_3 cholesterol and A-I levels are not affected.[47] HDL = high-density lipoprotein.

tients with hyperlipidemia to examine in detail the plasma lipoprotein changes as well as the mechanism of the HDL increasing effect.

In normolipidemic volunteers, Blum et al[31] indicated a counteracting effect of nicotinic acid on the HDL-decreasing activity of a high-carbohydrate diet. These investigators could clearly demonstrate that HDL catabolism was delayed by nicotinic acid administration and that the HDL_2/HDL_3 ratio in plasma, as determined by analytic ultracentrifugation, was elevated at least 300% after drug intake.

In healthy volunteers on a free diet, Shepherd et al[56] could confirm the HDL-elevating properties of nicotinic acid (3 g/day). The drug decreased plasma cholesterol 15% and triglycerides 27%; plasma HDL cholesterol was increased 23%, with a 345% increase in the plasma HDL_2/HDL_3 ratio (Fig. 6). This resulted from an absolute increment (+646%) in circulating HDL_2 and decrement (47%) in HDL_3 levels.

These investigators,[56] in types II and IV hyperlipidemic patients, could show somewhat divergent effects of nicotinic acid.[57] In the entire group of type II patients, only a reduction in plasma total triglycerides and VLDL cholesterol could be noted; no change was detected in total, LDL and HDL cholesterol levels. However, when

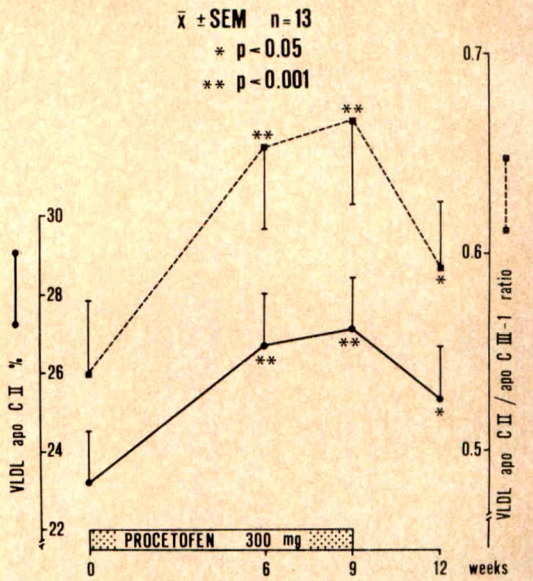

FIGURE 5. Progressive increase in the apoprotein C-II content and the apo C-II/C-III-1 ratio in very low density lipoprotein (VLDL) during fenofibrate (procetofen) treatment in patients with type IV hyperlipoprotenemia (same cohort as in Figure 4). Both apoprotein changes are reversible after the end of treatment. SEM = standard error of the mean.

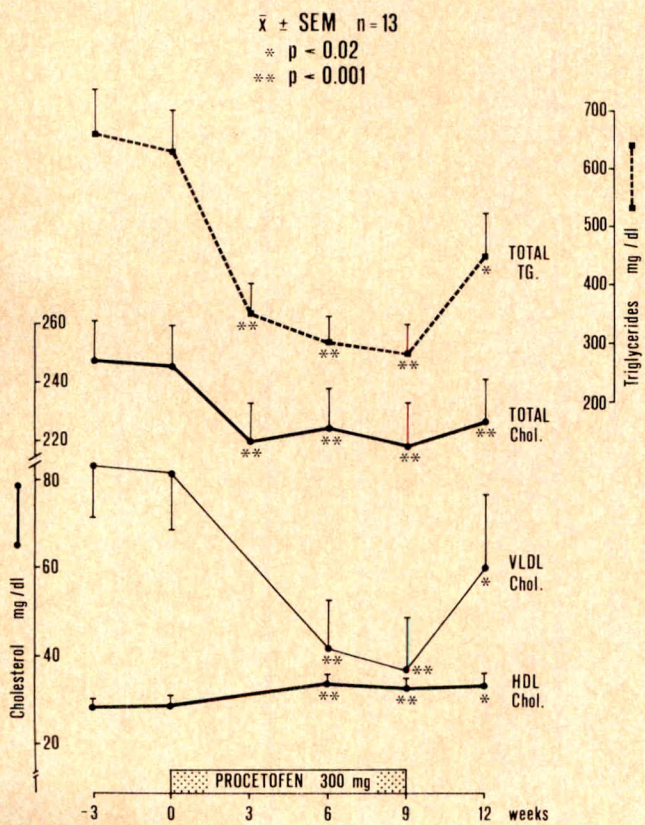

FIGURE 4. Plasma lipid and lipoprotein changes in patients with type IV hyperlipoproteinemia during and after the administration of fenofibrate (procetofen). An 11% increase in high-density lipoprotein (HDL) cholesterol may be noted, maintained after the end of treatment. Chol = cholesterol; TG = triglycerides; SEM = standard error of the mean; VLDL = very low density lipoprotein.

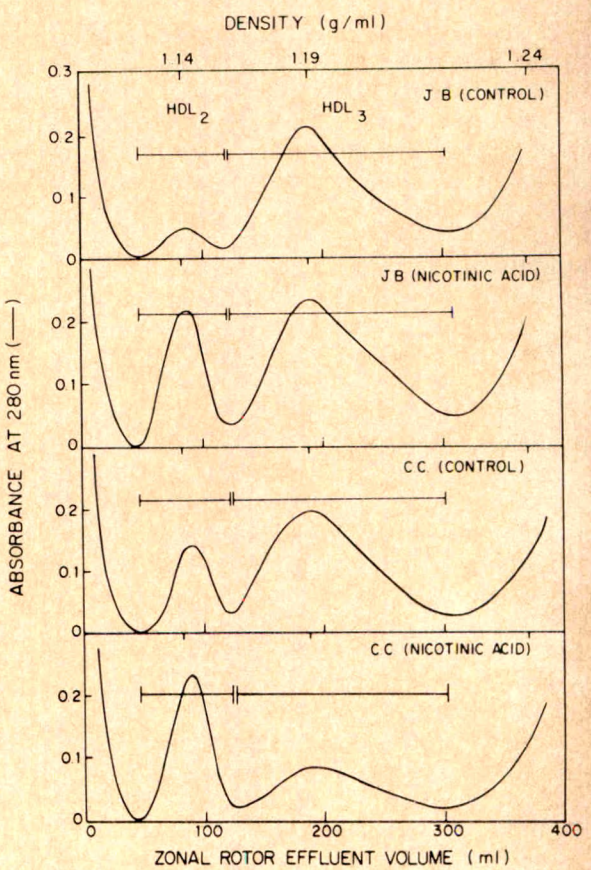

FIGURE 6. Separation of the high-density lipoprotein (HDL) subfractions by zonal ultracentrifuge before and after administration of nicotinic acid to normolipidemic volunteers. A dramatic increase in HDL_2 and a concomitant reduction in HDL_3 (particularly in subject CC) are noticeable.[56]

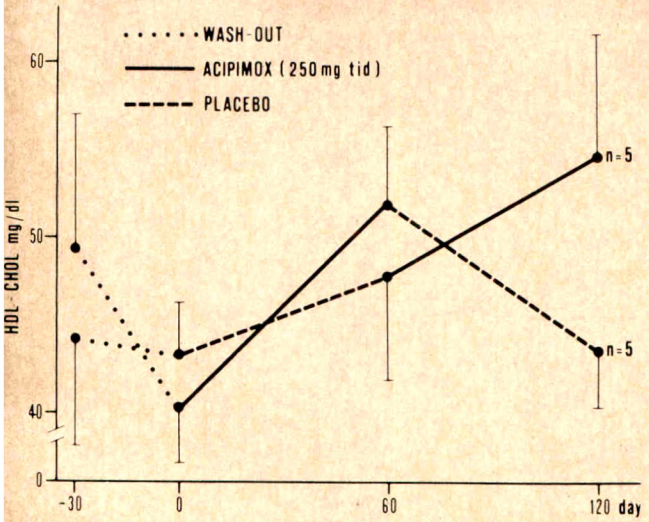

FIGURE 7. Changes in plasma high-density lipoprotein cholesterol HDL-CHOL levels in patients with type IIA hyperlipoproteinemia during a crossover trial of acipimox, a nicotinic acid analog, versus placebo. HDL cholesterol levels are about 20% higher during active drug treatment, the increase being reversible after the switch to placebo.[28] Tid = 3 times a day.

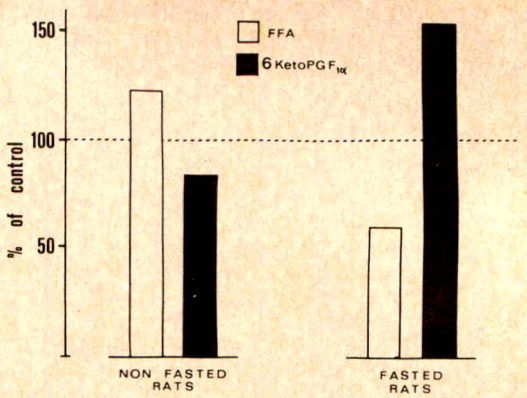

FIGURE 8. Free fatty acid (FFA) release from adipocytes and PGI_2 formation from adipose tissue arteries in rats treated with etofibrate (200 mg/kg). In fasted animals in which lipolysis is stimulated, an enhanced PGI_2 release together with FFA levels may be detected.[61]

only type IIA patients are considered, an increase in HDL cholesterol may be established (+37%) together with a striking increase (+510%) in the HDL_2/HDL_3 ratio. Patients with type IIB hyperlipoproteinemia were essentially insensitive to the lipid-lowering effect of the drug, and indeed, their HDL_3 levels increased 20%. Plasma lipid and lipoprotein changes in type IV patients were similar to those previously reported in normolipidemic subjects.[56]

Our findings with the nicotinic acid analog acipimox in hyperlipidemic patients are somewhat similar and somewhat at variance with those of Packard et al.[57] We failed to note any change in HDL cholesterol levels in type IV patients, whereas we did detect a significant increase in HDL cholesterolemia in type IIA patients (Fig. 7).[28] In this study, the reversibility of the HDL cholesterol increase (+20%) after the switch to placebo was clearly evident.

The mechanism whereby nicotinic acid increases HDL cholesterolemia may be linked to a reduced fractional catabolic rate of apoprotein A-I.[31] However, an increased HDL formation can be consequent also to stimulated VLDL lipolysis.[13] The inconstant effect on HDL cholesterol levels in the different hyperlipoproteinemia phenotypes is far from clear. It may generally be inferred that an increased formation of HDL_2 particles from HDL_3 is a frequent consequence of nicotinic acid treatment, thus possibly influencing plasma levels of the putative protective subfraction of HDL.

Etofibrate: This compound, despite extensive clinical experience, has not been the object of detailed investigations, particularly pertaining to the HDL lipid levels. In humans, as shown by Kaffarnik et al,[30] both plasma cholesterol and triglyceride levels are significantly reduced and the effect on HDL cholesterol, although consistent, is relatively small (around +10%). Similar findings, that is, an 18% reduction in total cholesterol with an 8% increase of HDL cholesterol, were recorded by Gustafsson[58] in patients with stable hypercholesterolemia; this author noted that plasma cholesterol had been decreased only 6% by previous clofibrate administration in the same cohort.

Aside from its lipid-decreasing activity, etofibrate is of interest because it shares with nicotinic acid the capacity to release prostaglandins from tissues and particularly from the arterial walls.[59] Our research group has placed particular effort into studies on the release of prostacyclin (PGI_2) from the arterial walls after the administration of nicotinic acid or etofibrate. PGI_2, an unstable metabolite of arachidonic acid, exerts powerful platelet antiaggregant and arterial vasodilator effects.[60] The release of PGI_2 from the endothelium after etofibrate administration is more prolonged than that exerted by nicotinic acid, owing possibly to the more stable plasma levels of nicotinic acid after the administration of etofibrate.[61] As shown in Figure 8, PGI_2 release from the arterial wall is particularly enhanced in fasted conditions in which adipose tissue lipolysis is stimulated and etofibrate is also capable of reducing free fatty acid levels.[61]

The potential capacity of drugs affecting HDL levels to stimulate PGI_2 release is a subject for future experimental and clinical studies. The 2 findings, elevated HDL levels and enhanced PGI_2 release, may be closely related because in mammalian species HDL are loaded with phospholipids rich in arachidonic acid.[62]

In conclusion, the increase in HDL cholesterol levels is a consequence of treatment with several pharmacologically active compounds. Although the mechanisms underlying this effect are not totally clarified, in most cases an activation of VLDL lipolysis, with consequent transfer of surface components to HDL, appears to be operative. Interestingly, PGI_2 release from the arterial wall may be stimulated by nicotinic acid derivatives as well as possibly by other hypolipidemic agents. Whether this vascular effect may partly explain the protective activity of HDL against the progression of atherosclerotic lesions remains to be established.

Influence of Clofibrate, Bile-Sequestering Agents and Probucol on High-Density Lipoprotein Levels

CHARLES GLUECK, MD

The management of lipid disorders has been greatly improved by advances in our understanding of lipoprotein metabolism. New developments in the isolation and quantitation of the lipoprotein apoproteins have shed light on their essential role in normal and abnormal lipid transport and have helped clarify the mode of action of lipid-lowering drugs. Excess lipid levels can occur because of overproduction, faulty degradation or defective removal of 1 or more lipoproteins.

Clofibrate appears to decrease levels of very low density lipoproteins (VLDL) and intermediate-density lipoproteins (IDL) by enhancing their intravascular degradation. Although it often slightly decreases low-density lipoprotein (LDL) levels, it may markedly increase LDL levels in patients with initially high VLDL levels. Its effects on high-density lipoproteins (HDL) are small, often increasing HDL slightly. Bile acid sequestrants act by enhancing the rate of removal of LDL. Their effects on VLDL and IDL are slight. In some subjects there is a moderate increase in both VLDL and IDL levels. HDL concentrations are increased minimally. Probucol's mechanism of action is still unclear, but it appears to enhance LDL removal. Its effects on VLDL and IDL are minimal. Of concern is the repeated observation that probucol reduces HDL concentrations by decreasing HDL synthesis. The resultant reduction in HDL concentrations often rivals its effect in decreasing LDL levels. Knowledge of the selective effect of lipid-lowering drugs on specific lipoprotein fractions is essential for their proper therapeutic selection.

The effects of clofibrate, bile acid–sequestering agents and probucol on high-density lipoproteins (HDL) will be discussed, followed by a description of gemfibrozil. I want to expand on a comment made by Dr. Lewis in this symposium and an additional question raised by Dr. Banta's comments. Although we are focusing on drugs and their effects on HDL, these drugs have pleomorphic effects on the lipoprotein family, and they must be considered simultaneously. Over the last 25 years many of us have been trying to provide conclusive evidence that a significant decrease in low-density lipoprotein (LDL) cholesterol will either retard the progression of atherosclerosis or induce its regression.[1–4] It is hoped that this question will be answered with the publication of the MRFIT studies and of the Lipid Research Clinics (LRC) program in 1984.

In addition to primary prevention of atherosclerosis with drugs in which LDL levels are decreased, many drugs are being evaluated, although not yet prospectively, in double-blind studies that will decrease triglyceride levels. Moreover, we should keep in mind an observation of low HDL cholesterol as a sole dyslipoproteinemia in subjects with premature coronary heart disease initially made by Nikkila[5] more than 20 years ago and recently brought home to us in our observation of familial hypoalphalipoproteinemia in children and their families with severe premature ischemic stroke:[6] that those persons with low HDL levels and otherwise normal lipids and lipoproteins are at high risk. There is a large population of persons with premature atherosclerosis who have normal total cholesterol, normal LDL and, usually, normal very low density lipoprotein (VLDL) levels and have as their characteristically abnormal lipoprotein low HDL of normal composition.[6] These families are riddled with premature heart disease and stroke. Some of the drugs we are discussing in this symposium have predominant effects on HDL and may be very useful in these persons.

Table I is a summary of the broad aspects of the various drugs we will discuss in this report, namely, clofibrate, the bile acid sequestrants, probucol and gemfibrozil. A few points of special interest will be discussed here.

First, there may often be a relative dissociation be-

From the Division of Lipid Research, General Clinical Research Center Division, University of Cincinnati, College of Medicine, University Hospital, Cincinnati, Ohio.

tween the effects of drugs on HDL and the effects of drugs on VLDL. Clofibrate, for example, has its predominant effect and use in decreasing VLDL and intermediate-density lipoproteins (IDL) (Table II).[7] It either decreases LDL modestly or, in persons with moderate-to-severe elevations of triglyceride, often elevates LDL or LDL apolipoprotein B, or both, an effect that may not be altogether desirable. Moreover, clofibrate has a relatively trivial effect, a plus-minus effect, on increasing HDL as compared with nicotinic acid, for example.

The bile acid sequestrants have, as their predominant effect, the effect being examined in the LRC trial and other trials—the lowering of LDL (Table III).[7,8] If anything, they modestly increase HDL levels in children and perhaps in young adults. In adults, bile acid sequestrants have a moderate effect—in most cases a very modest effect—and in patients with hypercholesterolemia, no effect on HDL levels.

Probucol, a recently released drug that significantly decreases LDL and has no effect on VLDL (Table IV), sharply reduces HDL,[7–9] so that the percentage reduction in HDL is greater than the percentage reduction in LDL, an effect that is puzzling and may be worrisome as well.

Gemfibrozil, a potent VLDL-lowering agent, perhaps similar in effect to nicotinic acid, has, like nicotinic acid, a very potent effect on increasing HDL. In our experience, gemfibrozil is also extremely effective in increasing HDL in persons whose sole lipoprotein abnormality is a low HDL level (Glueck et al, preliminary communication). Very much like clofibrate, and depending on the triglyceride level, gemfibrozil may either depress or slightly elevate LDL.

To comment briefly on the proposed mechanisms of action,[7] clofibrate appears to enhance the intravascular degradation of VLDL and LDL. The overall outcome of that effect is reflected in its depression of VLDL and IDL, which makes it so useful in familial type III disease. Unfortunately, perhaps as an outcome of this catabolic cascade, LDL levels and apo B in LDL are augmented particularly when the initial VLDL is elevated, and often there is an increase in biliary cholesterol, which leads to one of the major side effects of clofibrate, the effect on the gall bladder, and also to an increased amount of fecal neutral sterols that may essentially be related to the apparent increase of carcinoma reported in the World Health Study on clofibrate. Clofibrate, as already mentioned, has a plus-minus effect on HDL. As the VLDL, which was initially elevated, is reduced with clofibrate, there is often a modest, but certainly not dramatic, increase in HDL.

The proposed mechanism of action of the bile acid sequestrants is better understood: They enhance the removal of LDL.[7,8] It was recently shown that the administration of bile acid sequestrants in both normal persons and those with hypercholesterolemia leads to an induction of the apo B LDL-specific receptors, with enhanced catabolism of LDL. Hence, because such drugs have their predominant effect on LDL, it is not surprising that their effect on HDL is absent or minimal. Several years ago, Dr. Reginald Tsang and I made

TABLE I Effect of Lipid-Lowering Drugs on Lipoproteins

	Chylomicrons	VLDL	IDL	LDL	HDL
Nicotinic acid	+/—	↓↓↓	↓	↓↓	+/—
Clofibrate	---	↓	↓↓	+/—	+/—
Bile acid sequestrants	---	+/—	---	↓↓↓	---
Probucol	---	---	---	↓	↓
Gemfibrozil	+/—	↓↓↓	↓	↓	↑↑

HDL = high-density lipoproteins; IDL = intermediate-density lipoproteins; LDL = low-density lipoproteins; VLDL = very low density lipoproteins; ↑ = increase; ↓ = decrease.

TABLE II Clofibrate Profile

Proposed Mechanism of Action	Enhanced Intravascular Degradation of VLDL and IDL
Effects on lipoproteins	VLDL ↓ IDL ↓↓ LDL +/— often up when initial VLDL elevated HDL +/— often up when initial VLDL elevated

HDL = high-density lipoproteins; IDL = intermediate-density lipoproteins; LDL = low-density lipoproteins; VLDL = very low density lipoproteins; ↓ = decrease.

TABLE III Bile Acid Sequestrants (Cholestyramine, Colestipol) Profile

Proposed Mechanism of Action	Enhanced LDL Removal
Effects on lipoproteins	VLDL +/— IDL --- LDL ↓↓↓ HDL ---

HDL = high-density lipoproteins; IDL = intermediate-density lipoproteins; LDL = low-density lipoproteins; VLDL = very low density lipoproteins; ↓ = decrease.

TABLE IV Probucol Profile

Proposed Mechanism of Action	Enhanced LDL Removal; Decreased HDL Synthesis
Effects on lipoproteins	VLDL --- IDL --- LDL ↓ HDL ↓

HDL = high-density lipoproteins; IDL = intermediate-density lipoproteins; LDL = low-density lipoproteins; VLDL = very low density lipoproteins; ↓ = decrease.

TABLE V Nicotinic Acid Profile

Proposed Mechanism of Action	Decreased VLDL Synthesis
Effects on lipoproteins	VLDL ↓↓↓ IDL ↓ LDL ↓↓ HDL +/—

HDL = high density lipoproteins; IDL = intermediate-density lipoproteins; LDL = low-density lipoproteins; VLDL = very low density lipoproteins; ↓ = decrease.

an observation that has held up in several studies, although we cannot yet explain it, and it is that in children with heterozygous familial hypercholesterolemia, the bile acid sequestrants are often associated with a highly significant increase in HDL cholesterol, an increase that is continued throughout the dynamic change of HDL during adolescence. This is an area that perhaps deserves more evaluation.[10]

We know that if we enhance LDL removal, cholestyramine is a very effective agent in decreasing LDL. In the liver's attempt to respond to the bile acid feedback system, we often see an increase in VLDL and occasionally in IDL.

It is fair to say that probucol's proposed mechanism of action is still entirely speculative. I have offered some options here of enhanced LDL removal, which seems logical. I believe the studies by Nestel and Billington[11] show that initially this interesting drug decreases HDL synthesis. Probucol also probably decreases the synthesis of apo A-I. With probucol, what we see is an effect on 2 lipoprotein classes that may be independent. Certainly it substantially decreases LDL, although not nearly as much as cholestyramine or cholesterol resin, but probucol is easier to take, so the aggregate effect may be the same. At the same time, there is a proportionate, or perhaps a disproportionate, reduction in HDL cholesterol and apo A-I which, at least to extrapolate from the epidemiologic data, would not appear to be optimal in a pharmacologic agent.[7,8] I shall have further comments on this subject subsequently.

In summary, clofibrate has a modest to trivial effect on HDL, perhaps increasing it. Bile acid sequestrants have no real effect on HDL in adults; they produce a modest increase in HDL in children. Probucol produces a consistent 15 to 20% reduction in total HDL cholesterol and apo A-I.[9] Table V is a profile of nicotinic acid, which, among its other proposed mechanisms of action, probably decreases VLDL synthesis.

Influence of Gemfibrozil on High-Density Lipoproteins

CHARLES GLUECK, MD

In animal studies, gemfibrozil markedly elevates high-density lipoprotein (HDL) cholesterol levels. In humans with primary hyperlipoproteinemia and lipoprotein phenotypes IIA, IIB and IV, gemfibrozil, 1,200 mg/day, was associated with a 25%, 20% and 17% increase in HDL cholesterol, respectively. Gemfibrozil also substantially increased the ratio of HDL to total cholesterol, reflecting both an increase in HDL cholesterol and a decrease in very low density lipoprotein cholesterol and low-density lipoprotein cholesterol. Compared with a placebo in subjects with types IIA, IIB and IV lipoprotein phenotypes, therapy with gemfibrozil led to an increase of 33%, 34% and 23%, respectively, in the ratio of HDL cholesterol to total cholesterol. With gemfibrozil therapy, about 80% of subjects with hypertriglyceridemia had a reduction in triglycerides of 35% or a return to normal levels; 50% of subjects with hypercholesterolemia had a cholesterol reduction of 20% or a return to normal levels.

Gemfibrozil is a newly released drug that shows considerable promise. It is very intriguing for many reasons, particularly in the interaction of high-density lipoprotein (HDL) and very low density lipoprotein (VLDL) metabolism. Gemfibrozil is a chemical homolog of clofibrate and bezafibrate (Fig. 1). It is rapidly absorbed, plasma levels reaching a peak at about 1 or 2 hours after an oral dose, and tissue concentrations in animal models also peak rather briskly. I will summarize the animal studies on gemfibrozil available so far without going into the proposed or speculated mechanisms of each effect (Table I).

Gemfibrozil increases plasma HDL cholesterol in either the normal or the cholesterol-fed rat[1] and simultaneously produces a notable decrease in hepatic cholesterol[1,2] in the same rat model, accompanied by an increase in rat fecal sterol excretion. In normal female rats and in monkeys, gemfibrozil reduces plasma triglyceride levels, and in normal monkeys it produces a sustained reduction in these levels.[3] In normal rats, this drug is associated with a marked increase in lipoprotein lipase activity.

Table II presents a comparison of the results of 1,200 mg/day of gemfibrozil versus a placebo in a large multicenter study that will be described in more detail by other participants in this symposium.[4,5] There was a rather consistent percent change in triglyceride levels (Table III), a decrement of 40 to 45% by phenotype, and a rather substantive increase in HDL in each of these 3 groups. Although not shown here, preliminary data from our laboratory (Glueck and co-workers, preliminary communication) show a substantive increase of 20 to 25% in HDL in patients who have primary hypoalphalipoproteinemia without other recognized phenotypic lipoprotein abnormalities. As expected from the data in Table II, gemfibrozil compared with placebo increases the ratio of HDL to total cholesterol by as much as 20 to 30%.

I reiterate Dr. Barry Lewis' caveat that it has taken us almost 25 years to determine whether a reduction of low-density lipoproteins (LDL) will reduce atherosclerosis. It is hoped that it will not take another 20 years to determine whether increasing HDL will also be effective.

In terms of the mechanism of action of this interesting drug, we have limited but useful data. Nikkila et al,[6] in a study of a group of 20 subjects with hypertriglyceridemia, found a highly significant reduction of 45 ± 4% in triglyceride levels and a trivial reduction (11%) in total cholesterol, reflecting a decrease in VLDL but an increase in HDL. Postheparin lipolytic activity increased in 19 of 20 subjects, but this average increment of 18% was only marginally significant, and the decrease in triglyceride levels in these subjects in no way correlated with the increase in lipoprotein lipase. Interestingly and somewhat confusingly, given what we now know about the inverse relation of hepatic lipase to HDL, hepatic lipase levels increased in these subjects by 21%, but the decrease in triglyceride levels did not correlate with the increase in hepatic lipase. Nikkila et al[6] speculated that the substantial increase in VLDL catabolism was most likely not the major effect of

TABLE I Summary of Effects of Gemfibrozil in Animal Studies

Study	Effect
Plasma HDL in normal or cholesterol-fed rat	Marked elevation
Hepatic cholesterol in cholesterol-fed rat	Marked decrease
Rat fecal sterol excretion	Marked increase
Plasma triglycerides in normal female rat	Reduction
Plasma triglycerides in normal monkeys	Sustained decrease
Lipoprotein lipase activity in normal rat	Marked increase

HDL = high-density lipoprotein.

gemfibrozil treatment, but that the decrease in VLDL synthesis might well be a major effect.

Most animal studies indicate that gemfibrozil reduces hepatic triglyceride production by inhibiting peripheral lipolysis and decreasing the hepatic extraction of plasma free fatty acids and also by inhibiting the synthesis of VLDL carrier apoproteins, a series of effects some of which gemfibrozil may share with nicotinic acid. In human studies by Vessby et al[7] performed several years ago, adipose tissue lipoprotein lipase was not affected by gemfibrozil therapy. We do not yet have good evidence that gemfibrozil exerts its primary effect by increasing lipolytic activity.

We have been trained to look at HDL from an epidemiologic point of view in a cross-sectional or longitudinal window of static measurement.[8–10] I propose that we start thinking about HDL from a pharmacologic point of view. Some of the lessons we have learned from the epidemiology of HDL are obviously applicable to its pharmacologic aspects, but perhaps there will be some surprises. There is an array of disparate agents, including diphenylhydantoin, terbutylene, estrogen, DDT, alcohol and insulin, that have all been demonstrated in experimental studies in man to increase HDL cholesterol (Table IV). Gemfibrozil, nicotinic acid and Dilantin® share top billing in elevating HDL levels. We obviously have a very disparate group of agents. Moreover, there is clearly no one-to-one relation between agents that reduce VLDL and agents that increase HDL (Table IV). Thus, alcohol allows a comparison with gemfibrozil (Table IV). Alcohol, in controlled human experiments, elevates HDL, but generally potently elevates VLDL at the same time. Gemfibrozil and nicotinic acid are similar in that they increase HDL and depress VLDL simultaneously. Diphenylhydantoin has the very potent effect of increasing HDL, probably similar to the effect of DDT in its direct effects on the liver. Terbutylene, a beta agonist, is associated with increased HDL levels, whereas propranolol, a beta-blocking agent, is associated with reduced HDL levels. The list of agents that affect HDL cholesterol is growing, and clearly these agents mediate their effects on HDL and VLDL in very heterogeneous ways. I propose that by studying these types of agents, we can learn much more about the pharmacologic aspects of HDL and their relation to coronary heart disease.

It may be useful to carry out the same exercise with agents that depress HDL (Table V). Probucol is a drug designed to decrease LDL cholesterol levels, which is a therapeutic attribute,[11–13] while at the same time it substantially reduces HDL levels. Oxandrolone and stanozolol, synthetic anabolic androgenic steroids, and natural or synthetic progestin, despite depressing VLDL and augmenting lipolysis, nevertheless, mediate a decrease in HDL,[14] instead of causing the expected increase in HDL levels, probably by increasing hepatic lipase levels. Conversely, at least several agents, particularly the beta-blocking drugs, which substantially decrease HDL levels (similar to stanozolol), are asso-

ciated with increased VLDL levels.[15] Therefore, when we look at the drugs and environmental agents that affect HDL, we have to keep in mind the very diverse effects of these agents on the other lipoprotein groups, and perhaps by analyzing these compounds we can learn much more about the pharmacologic aspects of HDL.

Gemfibrozil increases the levels of HDL and apo A-I, which are beneficial effects, we believe, and decreases the levels of VLDL, also putatively a beneficial effect.[16–19] HDL is a whole family of lipoproteins busily changing coats, giving off cholesterol and phospholipids and exchanging apolipoproteins C and E with VLDL. It is never in the same place at the same time. Obviously, therefore, we are discussing a flux of a family of molecules. We can speculate that the increased levels of HDL cholesterol or apolipoprotein A-I with gemfibrozil may reflect, in part, increased synthesis of apo A-I or apo A-II, or both, increased nascent HDL or increased total HDL cholesterol levels, which presumably would provide us with more nascent HDL or more HDL molecules available for reverse cholesterol transport, for interaction with prostaglandin prostacyclins, for transport of arachidonic acid and for all the antiatherogenic aspects that have been reported, and presumably that would be good (Table VI). Conceivably, gemfibrozil could reduce the catabolism of HDL and thus, although producing a cross-sectional increase in HDL, could actually reduce reverse cholesterol transport (Table VI). This possibility is very unlikely but needs to be examined. Dr. Moti Kashyap and I are researching the effects of gemfibrozil on I^{125}-HDL turnover, to study this area.

Oxandrolone and stanozolol, in comparison (Table VI), depress HDL cholesterol.[13,14] We know that they substantially increase the activity of hepatic lipase[14] and therefore severely depress HDL. We would think that epidemiologically this effect may not be good. If they possibly depressed synthesis of HDL and reduced the total number of molecules available to do their job, that effect might be bad (Table VI). However, it is very likely that these 2 drugs may well increase the catabolism of HDL,[14] increase the fractional catabolic rate of HDL and, thus, increase the flux of return of HDL to the liver, which could possibly be good (Table VI).

TABLE VI Pharmacologic Mechanisms (Speculative) for Effects of Drugs on HDL Cholesterol*

	HDL Cholesterol	HDL Synthesis	HDL Catabolism	VLDL Cholesterol
Gemfibrozil	Up	Possibly increased (good)	Possibly reduced (bad)	Down
Probucol	Down	Probably decreased (bad)	Possibly increased (good)	No change
Oxandrolone	Down	Possibly decreased (bad)	Probably increased (good)	Down, LDL
Stanozolol (LPL Up+, HL++)				Up cholesterol

* Plus signs indicate relative strength of effect.
HDL = high-density lipoproteins; HL = hepatic lipase; LPL = lipoprotein lipase; VLDL = very low density lipoproteins.

Finally, probucol depresses HDL cholesterol, and on the basis of Nestel's work[20] we think this depression reflects a probable decrease in the synthesis of HDL cholesterol.

In summary, we are in the infancy of the pharmacologic study of drugs and environmental factors that affect HDL. These drugs inevitably and necessarily affect other lipoprotein classes. It may well take us 15 to 20 or 25 years to provide evidence that pharmacologic intervention in HDL levels may also lead to amelioration of atherosclerosis, evidence that I believe is becoming increasingly apparent in the treatment of LDL levels.[21]

Clinical Results With Gemfibrozil and Background to the Helsinki Heart Study

VESA MANNINEN, MD

The efficacy and safety of gemfibrozil in the treatment of dyslipidemia were investigated in a 6-year follow-up study of 254 patients with primary dyslipidemia. Most were middle-aged men with type IIA or IIB hyperlipoproteinemia. A significant correction in plasma lipid levels was seen in nearly 90% of all cases irrespective of the type of lipid abnormality. Overall, gemfibrozil therapy decreased levels of plasma total cholesterol 16%, triglycerides 45% and low-density lipoprotein (LDL) cholesterol 21%. The high-density lipoprotein (HDL) cholesterol concentration was increased 23%. The ratio of HDL cholesterol to total cholesterol increased from 0.13 to 0.20, approaching the value of matched controls in the population (0.23). Results in small pilot studies of patients with renal failure and uremia, the nephrotic syndrome or chemical diabetes were also encouraging. Plasma prekallikrein and kininogen values increased with gemfibrozil, possibly indicating correction of defective blood coagulation and fibrinolysis. Side effects were few; abdominal discomfort was noted in some patients and a skin rash in 2. In the intervention group, the number of myocardial infarctions was lower than expected (5 rather than 16). Results to date indicate that gemfibrozil effectively corrects most types of dyslipidemia, with minor side effects. The small number of observed myocardial infarctions supports the suggestion that an increase in HDL and a decrease in LDL levels during gemfibrozil therapy may be of clinical benefit in the prevention and management of coronary artery disease in subjects with dyslipidemia. The Helsinki Heart Study was designed as a definitive test of this hypothesis. This large, double-blind, placebo-controlled, primary (4,050 patients) and secondary (650 patients) prevention study is currently in progress.

After preliminary studies from several laboratories indicating the efficacy and safety of gemfibrozil in the management of hyperlipoproteinemia,[1] a major investigation involving a 6-month, placebo-controlled trial of 76 patients was initiated (Table I).[2] A total of 95 patients participated, but in 19 of them lipid values were controlled by the 3-month dietary instruction regimen preceding the study. Doses of 800, 1,200 or 1,600 mg/day of gemfibrozil were administered, and reductions in total cholesterol were achieved at each level. The 1,200-mg/day dose was deemed adequate from a clinical standpoint, for the additional benefit derived from the larger dose was small. Reductions in triglyceride levels were observed at all 3 doses, with the 1,200-mg/day dose providing a clinically satisfactory response. As a result, these patients were included in a long-term study using gemfibrozil at a dosage of 1,200 mg/day.

During the design of this study in 1975, the importance of high-density lipoprotein (HDL) cholesterol was not apparent. When it did become known, treatment was stopped in 51 patients. These subjects were followed up for 6 months, during which time their mean total cholesterol levels increased significantly (17%), whereas their mean HDL cholesterol levels decreased (−20%). It took 3 to 4 months for the gemfibrozil effect to stabilize. When treatment was reinstated, total cholesterol, HDL cholesterol and the HDL/total cholesterol ratio soon reached previous treatment values. These levels have subsequently been sustained for 3 years.

A total of 254 patients with type IIA and type IIB dyslipoproteinemia, mostly from the county of North Karelia but including some persons from Helsinki, were treated during the last 7 years. Gemfibrozil therapy produced a 16% reduction in mean total cholesterol, a 23% reduction in low-density lipoprotein (LDL) cholesterol, a 23% increase in HDL cholesterol and a 45% decrease in triglyceride levels (Table II). Plasma lipid values during gemfibrozil therapy were close to those in a matched reference group. Interestingly, the HDL/total cholesterol ratio, which was low in the be-

ginning, increased to a level close to that seen in the reference group. With certain reservations, this ratio may be the most reliable single practical parameter that can be used to indicate the degree of cardiovascular risk associated with dyslipidemia.

In more recent studies (so far mostly unpublished), we found that during gemfibrozil treatment, both major HDL apoproteins, apo A-I and apo A-II, are significantly increased (Table III). Similar confirmatory observations were reported elsewhere.[3,4] In a group of 12 male patients, both HDL_2 and HDL_3 subfractions were significantly increased during 3 months of gemfibrozil treatment[5] (Table IV). The absolute change in HDL_2 cholesterol was 0.1 mmol/liter and the change in HDL_3 0.2 mmol/liter. However, when these changes are expressed as percentages, they are greater in HDL_2 because its initial levels were low. The same plasma samples were analyzed in 2 different and independent laboratories using somewhat different techniques. The interlaboratory variation was practically negligible, strongly suggesting that such changes were real despite the small patient sample. Without complicated kinetic studies it is not possible to understand fully the mechanisms leading to increases in these HDL subfractions. However, it seems likely that in essence, HDL_3 synthesis is increased in the liver and, as a result of an increase in catabolic rate, more HDL_2 is formed.[5,6] Most investigators have found the strongest correlation between low HDL_2 levels and coronary artery disease.[5,7]

In a study of 60 subjects with dyslipidemia and previous myocardial infarction, the antidyslipidemic efficacy of gemfibrozil was similar to that reported for patients free from myocardial infarct.[8] In a pilot study of patients with renal failure and uremia or the nephrotic syndrome, response to gemfibrozil was good without drug-attributable side effects.[9,10] Results of studies in

C = cholesterol in various fractions; HDL = high-density lipoprotein; SD = standard deviation; TC = total cholesterol; TG = total triglycerides.

patients with chemical diabetes were also promising,[11–13] in that there was a clear-cut increase in HDL cholesterol and a decrease in triglyceride levels. Most patients were receiving dual therapy with gemfibrozil and tolbutamide.[13]

Gemfibrozil has been found to consistently increase both plasma prekallikrein and kininogen values.[14] Changes in the levels of HDL cholesterol and prekallikrein and in the levels of apoprotein A-I and kininogen correlated significantly. These changes in prekallikrein and kininogen are difficult to interpret, but they are consistent with a correction in impaired blood coagulation or fibrinolysis, or both.[15,16] With the recent finding of a high incidence of thrombi during the acute phase of myocardial infarction,[17] the current observations warrant further investigation.

During gemfibrozil administration no serious adverse reactions attributable to the use of the drug were seen in erythrocyte sedimentation rate, hematology, blood sugar or hepatic or renal function. Ophthalmologic examination did not indicate any organ damage. Gastrointestinal complaints, such as stomach pain and swelling, were somewhat more frequent among patients on active therapy compared with those taking placebo. Two patients had eczema, most likely attributable to gemfibrozil. Eleven had the drug withdrawn because of abdominal discomfort and 5 because of transiently elevated transaminase levels possibly due to alcohol consumption. Other dropouts resulted from nonresponsiveness to therapy, from moving out of the area or most often from the difficulties of frequent clinical visits in a rural area involving return distances of up to 90 miles.

No adverse drug interactions were observed between gemfibrozil and thiazides, furosemide, digoxin, beta-adrenergic blocking drugs, common spasmolytics, benzodiazepines or acetylsalicylic acid.

Helsinki Heart Study

Once clinical studies with adequate numbers of patients had confirmed the safety and efficacy of gemfibrozil in the management of most common types of dyslipidemia, our subsequent concern was to determine whether gemfibrozil therapy merely brought lipid levels to normal or whether it also offered some clinical benefit such as a reduction in cardiac events. According to statistical analyses, the expected number of myocardial infarctions in our treatment group was 16.[2] The lower incidence of 5, 1 of which occurred at the start of therapy and 1 in a patient who consistently failed to take the drug, encouraged us to undertake a placebo-controlled, prospective, double-blind study to test the assumption that correction of lipid abnormalities would reduce the risk of coronary heart disease and myocardial infarction.

With approval of the management and trade unions of the participating institutions, the Ethical Committee of the University of Helsinki and the Finnish National Board of Health, the Helsinki Heart Study was instituted under the supervision of an International Advisory Council chaired by Professor E. A. Nikkila. The Advisory Council consists of experts in metabolic disease, cardiology, biostatistics, epidemiology and chemical pathology and also contains the principal medical officers of the participating institutions together with representatives from Warner-Lambert Clinical Research (U.S.A. and U.K.). All Finnish members of the Advisory Council will constitute a Watch Committee responsible for ethical aspects in the continuation or termination of the study.

The study parameters were initially planned and calculated for a primary prevention study only (Table V). The secondary prevention group is a byproduct of the screening for the primary prevention study, as reflected by its size. However, because of the higher event rate, even the secondary prevention group should form the basis for a meaningful study.

All male employees aged 40 to 55 years from the Finnish Railways (8,000), Finnish Post and Telecommunication System (7,600) and 5 industrial companies (8,000) were invited to participate. From the total of 23,600 eligible men, 83% were willing to volunteer for the initial screening, which included analyses of total and HDL cholesterol levels and data on their general health and medical history. On the basis of the selection criteria of total low-density lipoprotein (TLDL) cholesterol (total minus HDL cholesterol), which had to be $\geq$5.2 mmol/liter, 7,000 men (30%) were admitted for the second screening, which included careful physical examination, electrocardiography, plasma lipid determinations (including triglycerides) and blood chemistry analyses. All lipid analyses have been and will continue to be performed in the same laboratory.

From this group, 4,700 men were eligible and willing to volunteer, 4,050 (17%) for the primary and 650 (2.7%) for the secondary prevention study. For final acceptance into the study, the volunteers had to have a TLDL cholesterol value of $\geq$5.2 mmol/liter, measured on 2 consecutive occasions 6 to 8 weeks apart. Such patients also had to be free from other major illnesses, but stable mild hypertension and chemical diabetes were not criteria for exclusion. Patients with coronary heart disease at entry were eligible for inclusion in the secondary prevention study (Table VI).

The investigation is a double-blind, placebo-controlled study in which half of the patients have been randomly assigned to active medication (gemfibrozil, 600 mg twice daily) and the remainder receive a matching placebo. Before allocation to treatment, patients in the secondary prevention group were stratified

TABLE V Parameters of the Helsinki Heart Study (Primary Prevention)

Parameter	Value
1. Study period	5 yr
2. Total dropout rate	20%
3. Annual placebo incidence of coronary heart disease events	1.5%
4. Reduction of coronary heart disease events (gemfibrozil versus placebo)	30%
5. Power (β = 10%)	90%
6. Level of significance (α)	1%
7. Number of men needed to meet these requirements	4,000

TABLE VI Number of Characteristics of Patients Enrolled in the Helsinki Heart Study*

Primary Prevention	Secondary Prevention
4,050 men	650 men
Age: 40–55 years at entry	Age: 40–55 years at entry
TLDL† ≥ 5.2 mmol/liter	TLDL ≥ 5.2 mmol/liter
No evidence of coronary heart disease	Evidence of coronary heart disease (ECG, history)
	Stratification for severity of coronary heart disease, age and smoking habits
Random allocation for gemfibrozil (1,200 mg/day) or for matching placebo	Random allocation for gemfibrozil (1,200 mg/day) or for matching placebo

* There will be clinical visits at 3-month intervals for 3 to 5 years. Endpoints will be either myocardial infarction or coronary death.

† TLDL = total cholesterol minus high-density lipoprotein cholesterol.

TLDL = total low-density lipoproteins.

for severity of coronary heart disease (previous myocardial infarction or history of angina), smoking habits and age. All patients will have clinical visits at 3-month intervals up to 5 years. The end points will be myocardial infarction or coronary death.

All patients will receive health education and will be prescribed a theoretically optimal diet. Because there are suggestions that dietary and biobehavioral modifications may themselves be effective to some degree,[18] pharmacotherapy alone was rejected on ethical grounds. Thus, the study should indicate any possible increase in protection against coronary events provided by gemfibrozil therapy over that provided by biobehavioral management alone. The study began in January 1981 and patient enrollment was completed in June 1982, with the exception of 90 patients in the secondary group enrolled in early November 1982. The investigation is in progress and is scheduled to last 5 years. Progress reports will be published at intervals.

Comments

The Helsinki Heart Study focuses on individuals at high risk for coronary heart disease so as to avoid difficulties of analysis due to concurrent illness, advanced age or dilution by low-risk individuals. As calculated from different sources and adjusted to the 1981 level, the annual mean myocardial infarction rate for Finnish men aged 50 years (mean age of the enrolled patients) is 10 per 1,000.[19,20] The incidence of coronary heart disease has been declining. However, the current decline has not solved the problem or removed the need for further attempts to improve the management of patients with coronary heart disease. Genetically, Finns are homogeneous, in essence 1 nation of 5 million inhabitants with the same hereditary origins. In contrast to some other countries, notably the United States, Finns aged ≥40 years also have a settled and stable lifestyle. In addition, most are concerned about their health. Thus, Finnish men should form a good group for a major prevention study on coronary heart disease, and almost 5% of the entire eligible male population (aged 40 to 55 years) has been screened.

Of the study parameters (Table V), the greatest errors may occur in the anticipated placebo incidence of coronary heart disease, which may not be as great as expected, and in the reduction of coronary heart disease events by gemfibrozil, which, in contrast, may be higher than predicted. With 1 year's results available from two thirds of the patients in the primary prevention group, it is already clear that the initial total cholesterol (7.7 mmol/liter, or 298 mg/dl) has decreased some 10% in the entire group (Dresner AJ, personal communication, 1982), suggesting a significant change in cholesterol values in patients on active treatment. Our main concern is to maintain scientific interest and enthusiasm among both staff and patients in a long-term study designed to solve a major medical problem.

Acknowledgment: The studies reported on have been performed in collaboration with M. Malkonen, MSc, A. Eisalo, MD, J. Virtamo, MD, I. Torstila, MD, S. Kaukola, MD, P. Kuusisto, MD, J. Tuomilehto, MD, and Ch. Ehnholm, MD, for the initial clinical phase. The Helsinki Heart Study is a joint effort involving the entire Advisory Council, the clinical research associates, the nurses and particularly the patients.

Clinical Results With Gemfibrozil

J. EDWARD PICKERING, MD

Gemfibrozil has been found to increase high-density lipoprotein (HDL) cholesterol levels in both animal and clinical studies. Although a reduction in saturated fat intake and a concurrent increase in unsaturated fat intake may reduce low-density lipoprotein (LDL) cholesterol values, the only dietary modification known to increase HDL is that resulting from significant weight loss. The Framingham study showed that the risk associated with HDL cholesterol (lower values, higher risk) is independent of the risk relative to LDL cholesterol (higher values, higher risk).

A multicenter trial in the United States showed a reduction of elevated serum triglyceride levels by more than 40% and of cholesterol to normal or by 20% in 50% of patients who received gemfibrozil, versus 25% of those who received a placebo. Gemfibrozil therapy reduced elevated serum very low density lipoprotein levels concurrently with triglyceride levels. It also increased serum HDL by approximately 20% and the HDL/total cholesterol ratio by approximately 30%. HDL cholesterol levels continued to increase for up to 2 years in the multicenter study. The increase over baseline levels was seen in all 3 types of hyperlipoproteinemia (IIA, IIB and IV).

The most common side effects were minor gastrointestinal symptoms and transient abnormalities in hepatic enzymes, which occurred in less than 3% of the patients. There were no other liver function abnormalities and no evidence that gemfibrozil induced liver toxicity. Gemfibrozil had a safety advantage over clofibrate, especially with regard to lithogenic potential. Gemfibrozil demonstrated a low side-effect profile and a positive influence on regulating lipoprotein levels in patients with hypercholesterolemia and hypertriglyceridemia.

The Multiple Risk Factor Intervention Trial has shown some of the limitations of environmental modifications of high-density lipoprotein (HDL) in that only a 2- or 3-mg/dl change (about 7 to 10%) has been achieved by 3 environmental modifications: (1) an increase in intake of alcohol, (2) a reduction of 10 pounds or more in body weight and (3) cessation of smoking. This study, which was designed to modify nutrition, lower cholesterol levels, modify smoking behavior and control cholesterol, did not have a component of exercise modification. Because of these limitations, our attention was then directed to the pharmacologic modification not only of total serum cholesterol, but also of HDL, and we, like others, have used gemfibrozil for this purpose.

This compound is similar to clofibrate but differs in potency, mechanism of action and therapeutic effects. The multicenter study of this compound involved 427 patients who primarily had type II hyperlipidemia; 215 had type II hyperlipidemia, with 108 of those having IIA and 107 having IIB. The remaining 212 had type IV hyperlipidemia. The mean lipid levels for those with IIA were: cholesterol 323 mg/dl and triglycerides 135 mg/dl. The principal results of treatment of this group were a reduction in cholesterol of approximately 5.4% in a 6-month-long trial and an increase in HDL of 22%. Those with type IIB had a mean cholesterol level of 318 mg/dl and a mean triglyceride level of 237 mg/dl. The mean cholesterol reduction in this group was 6.9%; triglycerides decreased markedly by 41%, and HDL increased 17%. The type IV group had a primary elevation in triglycerides. The mean triglyceride level was 319 mg/dl. They had only a modest decrease in cholesterol of 2%, whereas triglycerides decreased markedly and HDL increased substantially, about 24%.

These changes were compared with those from placebo, in which the changes in cholesterol were very brisk in the type II group and minimal in the type IV, as would be expected in that the type IV group had only a modest elevation in cholesterol (Table I). Similarly, an effect on triglyceride was noted both in the multicenter trial and in other protocols used for testing the effect of gemfibrozil on these 3 types of hyperlipidemia (Table II). Finally, the HDL cholesterol increased to its greatest degree in patients with type IIA and to a lesser

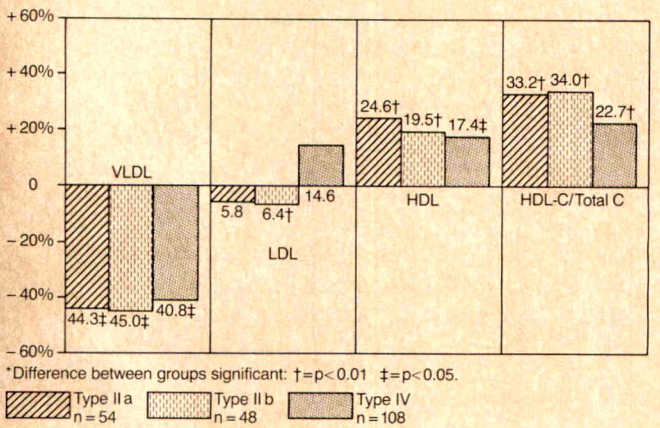

FIGURE 2. Summary of results with Lopid® in controlled phase of multicenter study. Average percent change from baselines at recommended dosage of 1,200 mg/day. C = cholesterol; HDL = high-density lipoproteins; LDL = low-density lipoproteins; VLDL = very low density lipoproteins.

degree with type IIB and type IV, but in all 3 groups there was a significant increase in HDL compared with placebo (Table III).

These results (Fig. 1 and 2, Tables I, II and III) show a decrease in triglycerides at a dose of 1,200 mg/day by type of hyperlipidemia, a modest decrease in cholesterol and a small decrease in total low-density lipoprotein (TLDL) (low-density lipoproteins [LDL] plus very low density lipoproteins [VLDL]), showing that most benefit was derived from the reduction in triglycerides (Fig. 1). As VLDL and LDL decreased, HDL increased and with this the ratio of HDL to total cholesterol improved (Fig. 2). This shows the effect of change with time in which the LDL decreased early and stayed down in all groups but tended to decrease even later after 10 months of administration, primarily in those with type

TABLE I Effects of Lopid® (1,200 mg/day) and Placebo on Serum Triglycerides

	IIB	−43.7	+0.8
	IV	−44.5	+14.9

TABLE II Effects of Lopid® (1,200 mg/day) and Placebo on Total Low-Density Lipoprotein Cholesterol Level (Multicenter Study)

Type	% Change	
	Lopid	Placebo
IIA	−10.3	−1.2
IIB	−13.4	+2.4
IV	−4.2	−1.2

TABLE III Effects of Lopid® (1,200 mg/day) and Placebo on High-Density Lipoprotein Cholesterol Level (Multicenter Study)

Type	% Change	
	Lopid	Placebo
IIA	+24.6	+1.3
IIB	+19.5	+8.0
IV	+17.4	+8.2

IIA. The HDL increased in groups, and again those with type IIA had the most beneficial late effect, with a peak at 5 months and then a secondary peak after 9 months.

There was a minimal change in glucose tolerance in that the group that received gemfibrozil had a somewhat higher level of blood glucose after glucose load when compared with those on placebo. The side effects with this drug were minimal, the most common being abdominal pain, and that was only slightly different from placebo; this abnormality was found in 3.8% of the gemfibrozil-treated patients versus 3.3% of those with placebo. Diarrhea was more common in the placebo group; epigastric pain was almost as common when compared with patients who received gemfibrozil. Therefore, we concluded that the administration of gemfibrozil markedly reduced the level of serum triglycerides and more moderately decreased the level of serum cholesterol. The drug was well tolerated. However, the level of blood sugar may increase, and it must be monitored.

Discussion—Effects of Pharmacologic Intervention on High-Density Lipoproteins

ANTONIO M. GOTTO, Jr., Moderator

Dr. Alan Howard (Cambridge, England): I would like to ask Professor Manninen a question about this new study that started in 1981. I notice that your exclusion point is greater than 5.2 low-density lipoproteins (LDL). Now gemfibrozil has only a modest effect on LDL. We have just seen that it lowers LDL by only 10%. Wouldn't it have been far better to look at people with either low levels of high-density lipoproteins (HDL) or high levels of very low density lipoproteins (LVDL), because these are the people you are actually going to be treating. It may be that you set up your experiment in such a way that you are studying the wrong population.

Vesa Manninen (Helsinki, Finland): That is a very good question and I really do not know how to answer it. Before we made a decision about the lipid parameter, we had lengthy discussions with experts on biometrics and with epidemiologists. We decided to have 1 single parameter, which was that the LDL cholesterol should be 5.2 or higher on 2 consecutive measurements; but of course there are arguments against this.

Dr. Gotto: I would like to ask 1 question of the investigators who have worked with gemfibrozil. Several points have been made concerning a comparison between this drug and clofibrate. The drug is not halogenated. I wonder if you have data on whether gemfibrozil produces a lithogenicity of the bile that is seen with clofibrate. Have you observed an increased incidence in gallstones? Thirdly, have the effects on the induction of peroxisomes, similar to the effects seen with clofibrate, been looked for with gemfibrozil?

Dr. Manninen: In our studies, we have not noted any problem with gallstones. The literature shows that gemfibrozil may be less lithogenic than clofibrate, and the data presented show that. These studies have been on healthy volunteers, and I think Dr. Marcus may know more about them.

Ed Marcus (Warner-Lambert, Morris Plains, New Jersey): As a physician I did some work in the United States with the 427 subjects whom Dr. Pickering referred to, and we were interested in the possible development of gallstones in these patients. Therefore, on baseline, before admission, we did cholecystograms; usually oral, in each of these subjects, eliminating from the study those with stones, and proceeded to reevaluate annually those who remained in the study. Our incidence of new gallstone formation at the end of 1 year was approximately 1.5%, and at the end of 2 years an additional 1% of the subjects developed evidence of either new gallstones where none had appeared previously or a considerable enlargement of minuscule or small stones that were present earlier. Whether this represents a lithogenic potential comparable to that of clofibrate I cannot say. It may well be that gemfibrozil has only limited lithogenic potential.

Dr. Gotto: Thank you. Dr. Little.

J. Alick Little (Toronto, Ontario, Canada): One problem I am presented with quite often when dealing with patients with marked hypertriglyceridemia who have already had pancreatitis is in prescribing a drug that may be either lithogenic or associated with increased pancreatic disease, as in the coronary drug trials. Has anyone had any experience with prescribing this or related drugs to patients who have already had pancreatitis?

Dr. Gotto: Dr. Lewis?

Barry Lewis (London, England): I would take the opposite view that one clear indication for this group of drugs is a patient with severe endogenous hypertriglyceridemia who has already had or has the risk of acute pancreatitis.

I think the structure of the symposium has caused many of us to be rather more speculative than we would have liked. I wonder whether I could pose a question I think might be of practical importance to us, namely, what would the panel feel are the indications for the CPIV group of drugs: severe hypertriglyceridemia, a type III, more generally for hyperlipidemia?

Dr. Gotto: Thank you. Professor Paoletti, shall we start with you?

Rodolfo Paoletti (Milan, Italy): The question is, what are the indications of the CPIV-related drugs? I think we have to postpone a final reprise of this question until we know how they affect arterial lesions. In this symposium will be presented some of the first studies showing that drugs like fenofibrate and nicotinic acid combined may cause regression in human femoral arterial lesions in a fairly short time. I refer to the preliminary work of Dr. Olsson in Sweden, for instance, and a study like this can easily be repeated for a number of drugs. We have 2 purposes: to assess the efficacy and to compare drugs with completely different modes of action. Until the preliminary part of the study is terminated, we are in no position to assess which drug is the best for which type of lipid or arteriosclerotic high-risk condition.

Dr. Gotto: Dr. Glueck, what are your indications?

Charles J. Glueck (Cincinnati, Ohio): I agree with Professor Paoletti's comments, but one then faces the conundrum of waiting to institute therapy until all the data are in relative to these specific agents. I believe that individuals who had severe primary depression of HDL cholesterol and/or atherosclerosis and a strong family history of atherosclerosis would not respond to environmental modifications. I certainly think that the use of gemfibrozil- or bezafibrate-type drugs that might raise HDL significantly would be appropriate, but without any conclusion about the antiatherogenic effect. We obviously do not have the data. In individuals who have substantial endogenous hypertriglyceridemia coupled with less than the tenth decile HDL cholesterol, who are unwilling or

unresponsive to diet or weight loss and who also have a strong family history of heart disease, you could make a reasonable case for carefully controlled intervention, again with the same caveat. We do not yet have any data, short of some of Dr. Blankenhorn's preliminary data with nicotinic acid, suggesting that such drugs reverse or retard the progression of atherosclerosis. However, I think there is a reasonable belief that such things might occur, and there are enough preliminary data of the type Dr. Blankenhorn produced in his studies—the type that Dr. Paoletti referred to—that in those 2 types of individuals the indication for treatment would be available. One could ask the same question about LDL. Do we yet have smoking-pistol evidence that primary prevention and lowering of LDL will ameliorate coronary heart disease in atherosclerosis? I suggest the answer to that is, not yet. Yet, I also suggest that most of us, when faced with men who have primary elevations of LDL and in whom diet alone will not work, are using drugs.

Dr. Manninen: My view is that we start with health education. We need more effective methods to change a nation's or an individual's habits. We cannot do that in a short period of time; it would take decades. Perhaps we do not have a basis for changing those habits too drastically. We have to start with these advances in health education and then if we have patients who do not respond to them, we can do something for them. The category we have forgotten includes the young and middle-aged individuals with type IIB who are at the highest risk. They have elevated LDL, elevated VLDL and low HDL. I believe we should have a fresh look at the treatment in these patients.

J. Edward Pickering (Philadelphia, Pennsylvania): To the degree we believe in the hazards of risk factors, we have to make quantitative changes to bring people to low-risk status. So far, we have not been able to do that with a large enough number of people with the Multiple Risk Factor Intervention Trial, and for those reasons we have an interest in pharmacologic modification.

Oli Fergamen (Denmark): In the back of all our minds are the problems posed by the WHO clofibrate study and the very serious side effects that seem to be engendered by long-term treatment with clofibrate. However, another development in the last year that we have not mentioned up to now is the results of the Oslo diet-cigarette study. The Oslo group demonstrated a 45% reduction over 5 years in sudden death or acute myocardial infarction, fatal and nonfatal, in some 600 men between the ages of 40 and 49 years who were in the high-risk group as defined by cholesterol levels. When that study is taken into consideration, as you must when designing large drug studies, you get some idea of the relative worth of pharmacologic versus dietary reduction of lipids. I am sure the Helsinki Heart Study was planned long before the results of the Oslo Heart Study were in, but I would be very interested to hear what kind of considerations Dr. Manninen and his colleagues were forced to make after the results of the Oslo Heart Study came out.

Dr. Gotto: Dr. Manninen, do you or Dr. Nikkila want to respond to that question? Have you made any modifications in your basic plan as a result of the Oslo Heart Study?

Esko A. Nikkila (Helsinki, Finland): I think not, because what we tried to look for in this study was the effect of a drug. As Dr. Manninen already mentioned, we just wished to study the effect of reducing the LDL and increasing HDL. We did not screen the triglycerides, but we just screened the difference between the total and the VLDL.

Dr. Rifkind (Rockville, Maryland): I would like to comment on the response to the question about therapy of subjects with hypolipidemia. Certainly, there is a dilemma in encountering a high-risk subject with hyperlipidemia and wondering what one should do for him. The temptation is always to say, since the patient is at high risk, we'll use the latest agent available that may have some efficacy. But I remind myself that we have a whole series of drug hyperlipidemic studies behind us that have given rise to a series of toxic problems; for example, the Coronary Drug Project in high-dose and low-dose estrogen, the Coronary Drug Project in the use of dextrothyroxine and subsequently with clofibrate and then the WHO clofibrate study. They have all shown that the toxic problems have to be weighed against possible and as yet unproved benefits. I caution the group on advocating the use of hypolipidemic drugs until we have the results of systematic studies such as the Helsinki study. As far as the comment about the pressure to use drugs because environmental modifications take a long time, I would like to echo the comment made by the previous speaker. I hope to show in my own presentation that if we look at the results of a large number of dietary studies—especially when we contrast them with a variety of lipid studies, the dietary studies are generally effective and sometimes surprisingly effective in lowering cholesterol, and broad-scale lipid studies are generally ineffective or at best disappointing.

Dr. Gotto: The problem is that we just do not have safe and effective drugs for lowering cholesterol by 30 or 40%. If we had such drugs, then it probably would not take hundreds of millions of dollars, thousands of subjects and years of study to try to answer these questions.

Sanders Williams (Durham, North Carolina): Dr. Manninen presented some interesting data and alluded to some effects on fibrinolysis. Have you taken direct measurements of fibrinolytic activity in response to gemfibrozil?

Dr. Manninen: No, we have not. That is speculation to speak about this correction of defective fibrinolyzers.

Dr. Williams: Yes, I agree. It is a very interesting speculation.

Dr. Manninen: However, the speculation is based on similar findings with clofibrate, and I believe that Calvalio in Boston has really achieved similar results with clofibrate.

Dr. Marcus: I want to respond to the chairman's request for some information about peroxisome changes in human subjects. An article by Dr. Felix de la Iglesia in the current issue of *Atherosclerosis* addresses this problem or the situation. We have studied 9 patients who have had gemfibrozil for up to 3 years, and subjects with liver biopsy did not show any of the peroxisome changes that were seen in male rats. This finding simply indicates our concern and interest in showing that there are differences in the 2 species.

Günter Schlierf (Heidelberg, West Germany): My remark will be very brief and addresses the question of indications for drugs. I think it depends on the risk you want to treat. The primary prevention study of Dr. Oliver was a study in which the lipid-lowering drug was used in people who did not have real hyperlipidemia, so there were side effects in all of them. Therefore, I essentially agree with Dr. Lewis. If we have subjects with hyperlipidemia, the indication is for lipid-lowering drugs in particular, compared with other risk factors. We have to look at the side effects. Some drugs have fewer side effects, and when we know them we can decide which drugs to use.

Manheim (Manheim, Germany): I have a question for Dr. Paoletti. You indicate that changes in apolipoproteins A1 and A2 with bezafibrate might indicate an increase in HDL_3 rather than in HDL_2. There is direct evidence by Professor Schwein in Munich that, in using the preparative ultracentrifuge, HDL_2 increases rather than HDL_3. Nevertheless, if you assume an increase in HDL_3, what mechanism would you propose? You also showed that the major mode of action of this drug is an increase in lipolytic activity.

Dr. Paoletti: I tend to believe that the mode of action of the drug is exerted mainly on the lipolytic activity, and the effects on the HDL_2 and HDL_3 are probably not an essential part of the mode of action. Unfortunately, the data available even in animal studies do not explain sufficiently clearly how the HDL in synthesis or formation is increased. Is this a direct mechanism or an aspecific mechanism? However, I would like to remind everyone that the list of drugs that affect HDL is extremely long and includes agents such as dioxin, which are pollutants. Certainly we do not necessarily have to find the mode of action for important drugs acting against atherosclerosis essentially in the formation or accumulation of HDL.

Dr. Gotto: I would like to reemphasize the great heterogeneity of the HDL subfractions. We have simplified them today by calling them HDL_2 and HDL_3, but there certainly are further subfractions. Dr. Patsch in Houston has shown that HDL_3 is clearly divided into at least 2 subfractions. We know there are at least 4 different sources. We do not know the sites of catabolism of HDL, and so there are multiple sites where drugs, exercise and diet can affect different sources of HDL and different subfractions.

Dr. G. Michael B. Berger: (Capetown, South Africa): I would like to go right back to Dr. Little's question about the treatment of hypertriglyceridemia, at least for acute pancreatitis. Very briefly, in our experience almost invariably the hypertriglyceridemia that causes pancreatitis of the severe exogenous type responds extremely well to a very low fat diet if you can obtain compliance, and it does not respond to drugs such as clofibrate. This response even applies to patients with hyperchylomicronemia unassociated with low lipoprotein lipase activity.

Dr. Gotto: Yes. Dr. Glueck and others have also shown that oxandrolone and the progestational agents such as norethindrone acetate are effective in exogenous hyperlipidemia.

I would like to express our gratitude to Parke-Davis and Warner-Lambert for making this symposium possible.

A THERAPEUTIC STEP AHEAD

LOPID®
(gemfibrozil)

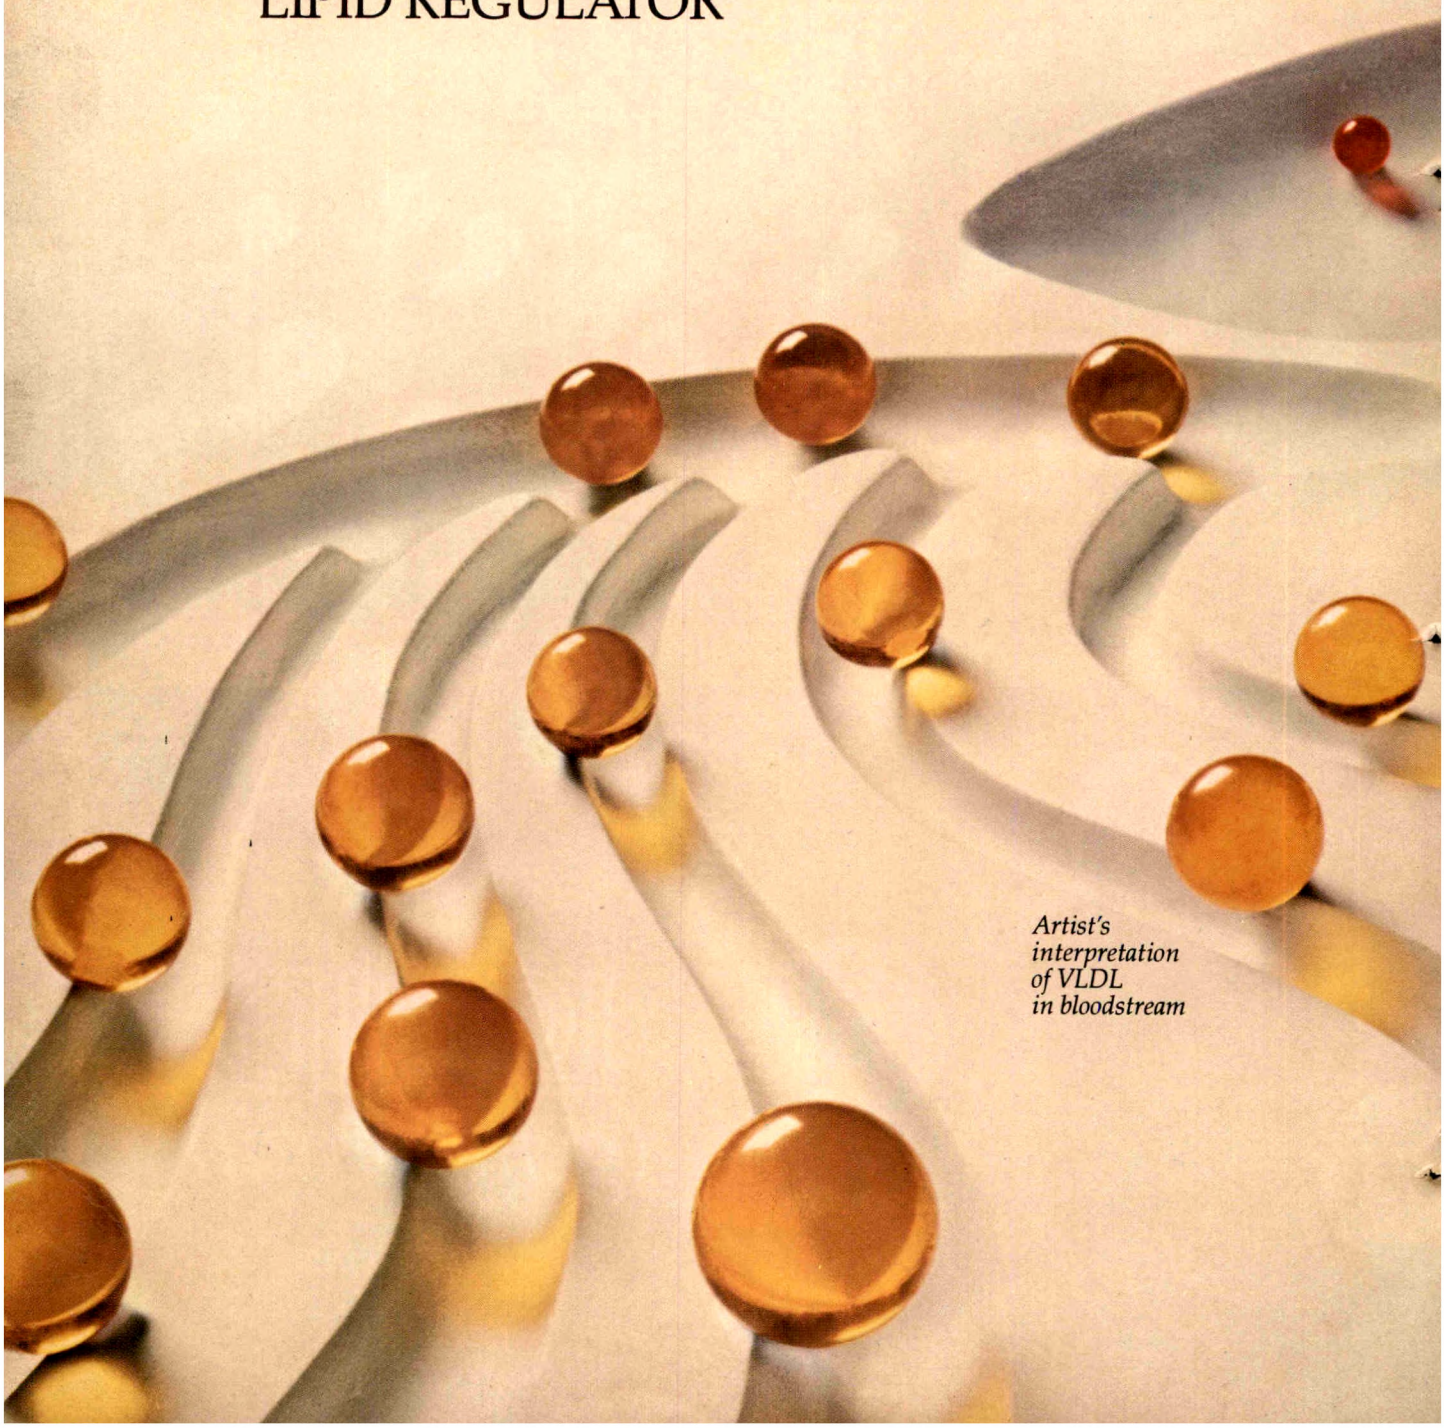
MORE THAN A LIPID-LOWERING AGENT— A TWO-WAY LIPID REGULATOR

Favorably regulates the balance of lipid fractions in certain dyslipidemias:

1/LOWERS elevated serum levels of triglyceride-rich VLDL and, to a lesser extent, cholesterol-rich LDL (very-low- and low-density lipoproteins implicated in dyslipidemia)

2/May also RAISE serum levels of HDL (high-density lipoproteins believed to transport cholesterol to the liver for catabolism and excretion)

LOPID is indicated for treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of pancreatitis and who do not respond adequately to diet.



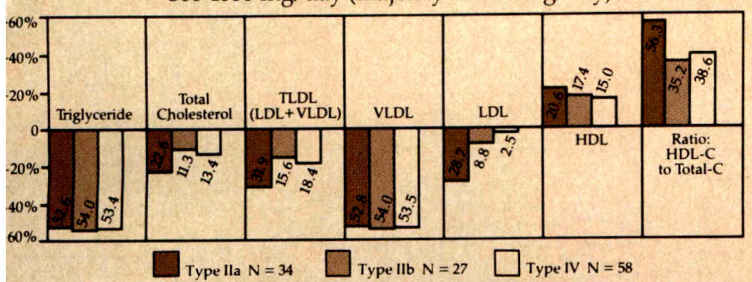
Artist's interpretation of VLDL in bloodstream

12.1.84

Lipid-regulating efficacy demonstrated in 1,437 patients with dyslipidemia[1]

Results of open-label phase of US multicenter study (119 patients) at end of 12 lunar months*

Average % change from baseline at doses ranging from 800-1600 mg/day (majority at 1200 mg/day)†



*Visit every 4 weeks during long-term use of LOPID.

†Data cited on this graph reflect clinical experience based on the multicenter trial. They do not imply an indication for Types IIa and IIb dyslipidemias.

Well tolerated, well accepted in clinical trials[1]

Profile of side effects similar to that of placebo.

No significant abnormalities seen in clinical and laboratory evaluations.

Less than 1% patient dropout in largest US study.

Convenient BID dosage

Diet, exercise, and weight loss are the first choice in therapy of lipid disorders.

© 1983 Warner-Lambert Company

LOPID®
(gemfibrozil)
A LIPID REGULATOR

LOPID® (gemfibrozil) Capsules

Before prescribing, please see full prescribing information.
A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO: HDL Cholesterol / Total Cholesterol
		Total	VLDL	LDL	HDL	
IIa	−44%	−4.2%	−44.3%	−5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	−6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (See WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis—LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy**—Before instituting LOPID (gemfibrozil) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy**—Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Seasonal Variation of Lipid Levels**—LOPID is not expected to alter seasonal variations of higher serum lipid values in mid-winter and late summer or the lower values in fall and spring.

4. **Impairment of Fertility**—Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. **Liver Function**—Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. **Cardiac Arrhythmias**—Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria
Central Nervous System: headache, dizziness, blurred vision
Musculoskeletal: painful extremities
Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia
Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints
Central Nervous System: vertigo, insomnia, paresthesia, tinnitus
Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)
Miscellaneous: fatigue, malaise, syncope

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

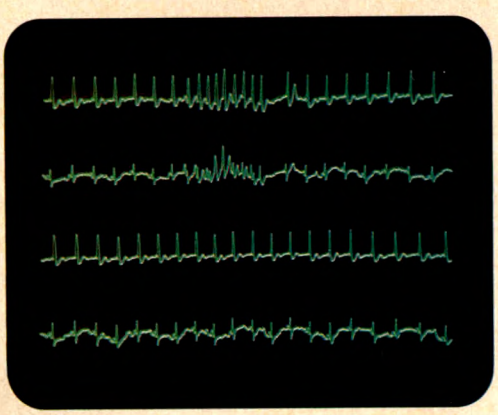
comp-scan™

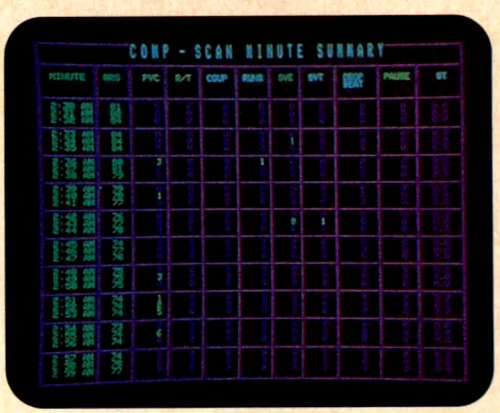
Holter Analysis System
Confidence in Computer Accuracy

Comp-Scan's exclusive minute-to-minute summaries give you clear, concise information that you can rely on. The minute-to-minute summaries are totally verifiable, allowing you to quickly check the computer's data against the ECG data for accuracy.

For hourly and average data, the Comp-Scan can generate four types of 24-hour final reports. These final reports can be generated in as little as six minutes and make excellent diagnostic tools. Hard copies of the final reports aid in future comparison and medical management of the patient.



ECG Paging Screen
Data can be displayed in full disclosure format for computer verification.



Minute-to-Minute Summary
Every minute from the 24-hour computer analysis can be reviewed for accuracy.

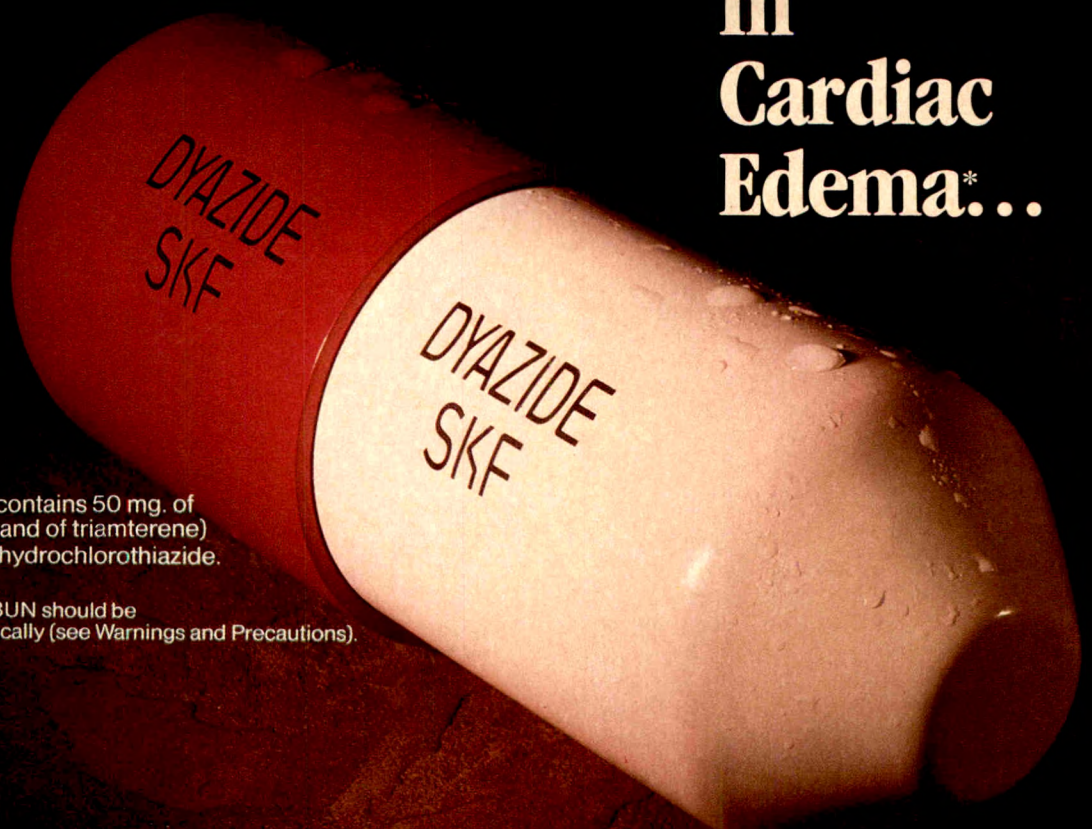
In Cardiac Edema*...



Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

Serum K^+ and BUN should be checked periodically (see Warnings and Precautions).

When You Need to Conserve K+

Over 17 Years of Confidence

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

WARNING

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

(particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, Dyazide should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on Dyazide when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with Dyazide. The following may occur: transient elevated BUN or creatinine or both; hyperglycemia and glycosuria (diabetic insulin requirements may be altered); hyperuricemia and gout; digitalis intoxication (in hypokalemia); decreasing alkali reserve with possible metabolic acidosis. Dyazide interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with Dyazide, but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and

measures and Dyazide should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Dyazide should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances; postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on Dyazide, although a causal relationship has not been established.

Supplied: Dyazide® is supplied in bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

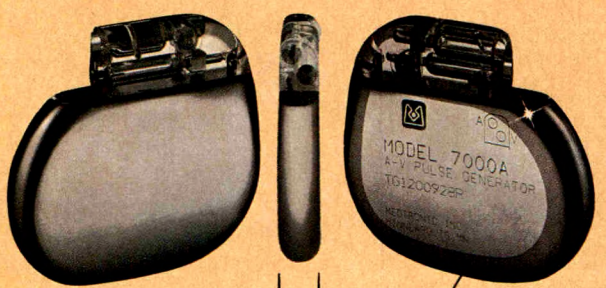
New VERSATRAX II

	340 ms.	A-V Sequential Pacing following a PVC...	235 ms.
THE FEATURE:	Atrial Refractory 340 ms. after a PVC...		Automatic Atrial Refractory adjusts to 235 ms. during A-V synchrony...
PATIENT BENEFIT:	To block sensing of retrograde when your patient needs it most	To restore synchrony	To track rapid atrial rates

Keeps a heart beating like a heart.

The most physiologic pacemaker.



New Versatrax II Model 7000A is:

- **Automatic Atrial Refractory**
  The advanced physiological method of tracking the atrium and discriminating retrograde
- **Smallest**
  The most physiological size and shape available
- **Superior Sensing Performance**
  Medtronic's exclusive patented circuitry rejects most myopotentials
- **Plus . . . uniquely from Medtronic**
  - A-V Pacing System Analyzer—Model 5311
  - Endocardial screw-in leads—Models 6957/6957J
  - Follow-up choices—Cardiocare™/Teletrace™
  - Educational programs
  - Service options
  - Proven reliability

Versatrax™ II Model 7000A Universal A-V Pacemaker

Intended Use

The Model 7000A universal A-V pulse generator has a wide range of application in patients requiring permanent cardiac pacing where restoration of A-V synchrony and/or sinus modulated rate variability is indicated to improve cardiac output or to protect against arrhythmias related to the sequence of cardiac impulse propagation.

With the Model 7000A programmed in the A-V universal (DDD) mode, indications may include:

- Some of the sick sinus syndrome conditions such as intermittent sinus bradycardia, sinus arrest or SA block.
- Intermittent or complete atrioventricular block with normal sinus activity.
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V interval settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

In the A-V sequential (DVI) mode, the Model 7000A may have application in the following:

- Sick Sinus Syndrome (sinus bradycardia, sinus arrest, SA block, and the brady-tachy syndrome).
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V delay settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

At any time, the Model 7000A can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry (e.g., atrial lead malfunction).

Contraindications

General: There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician.

DDD Mode: The DDD mode is contraindicated in the presence of atrial fibrillation, atrial flutter and rapid atrial rhythms or slow retrograde conduction.

DVI Mode: In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation or flutter.

Warnings

Diathermy: Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site.

Electrosurgical Units: Electrosurgical units should never be used in the vicinity of unipolar pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead.

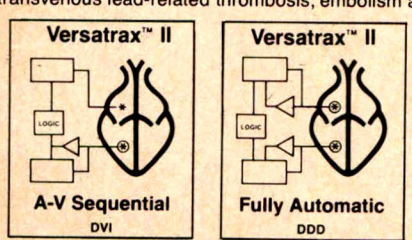
Defibrillation: Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. Positioning a magnet or the programming head over the pulse generator makes it subject to programming. A nominal vertical magnetic field strength of 90 Gauss (in a field measured 1½ inches from the magnet's surface) from a magnet at 1¼ inches from the reed switch is required to initiate asynchronous pacing. Do not use electrocautery, diathermy, or any other source of electromagnetic interference in the vicinity of the patient once a magnet or programming head has been positioned over the pulse generator. If an electrocautery unit is used, the physician may prefer to program the pacemaker to asynchronous pacing prior to the procedure.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.



Inter-Society Commission for Heart Disease Research Code.

CONTENTS IN BRIEF SEPTEMBER 1, 1983 • VOLUME 52 • NUMBER 5

A note from the Editor-in-Chief, William C. Roberts, MD, appears on page A14 of this issue.

Coming September 22: Perspectives on the Treatment of Ventricular Arrhythmias.

CORONARY HEART DISEASE

431 **Effect of Interventions in Salvaging Left Ventricular Function in Acute Myocardial Infarction: A Study of Intracoronary Streptokinase.** Florence H. Sheehan, Detlef G. Mathey, Joachim Schofer, Hans-Joachim Krebber, and Harold T. Dodge

439 **Hemodynamic Effects of Intravenous Prostacyclin in Stable Angina Pectoris.** Brian G. Firth, Michael D. Winniford, William B. Campbell, and L. David Hillis

444 **An Improving Prognosis Over Time in Medically Treated Patients With Coronary Artery Disease.** David B. Pryor, Frank E. Harrell, Jr., Kerry L. Lee, Robert M. Califf, and Robert A. Rosati

449 **Directional ST-Segment Deviation in Graded Exercise Tests Correlated With Motion of the Individual Segments of the Left Ventricular Wall.** James N. Karnegis, John Matts, Naip Tuna, Kurt Amplatz, Richard B. Moore, Henry Buchwald, and the POSCH Group

453 **Hemodynamic Effects of Felodipine at Rest and During Exercise in Exertional Angina Pectoris.** Jean-Marie Detry, Patrick M. De Coster, and Jean Renkin

458 **Morphology of Ventricular Premature Beats as an Aid in the Electrocardiographic Diagnosis of Myocardial Infarction.** Harold Dash and Thomas J. Ciotola

462 **Prognosis After an Initial Non-Q-Wave Myocardial Infarction Related to Coronary Arterial Anatomy.** Michael R. Nicholson, Gary S. Roubin, Louis Bernstein, Phillip J. Harris, and David T. Kelly

466 **Effects Induced on Blood Platelets in Ischemic and Nonischemic Myocardium.** Erik Thaulow

470 **Clinical Data Versus Noninvasive Testing as an Estimate of Coronary Status.** Samuel H. Brooks, John W. Allen, W. Allan Edmiston, Francis Y. K. Lau, and David H. Blankenhorn

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

477 **Role of a Catheter Lead System for Transvenous Countershock and Pacing During Electrophysiologic Tests: An Assessment of the Usefulness of Catheter Shocks for Terminating Ventricular Tachyarrhythmias.** Lawrence E. Waspe, Soo G. Kim, Jeffrey A. Matos, and John D. Fisher

485 **Significance of Prolonged Electrocardiographic Pauses in Sinoatrial Disease: Sick Sinus Syndrome.** Meir Mazuz and Howard S. Friedman

490 **Cardiac Arrhythmia and Conduction Disturbances During Sleep in 400 Patients With Sleep Apnea Syndrome.** Christian Guilleminault, Stuart J. Connolly, and Roger A. Winkle

495 **Encainide for Refractory Ventricular Tachyarrhythmia.** Brian Chesnie, Philip Podrid, Bernard Lown, and Ernst Raeder

501 **Induction of Clinical Ventricular Tachycardia Using Programmed Stimulation: Value of Third and Fourth Extrastimuli.** David E. Mann, Jerry C. Luck, Jerry C. Griffin, John M. Herre, Marian C. Limacher, Sharon A. Magro, Nancy W. Robertson, and Christopher R. C. Wyndham

507 **Hemodynamic Effects of Encainide in Patients With Ventricular Arrhythmia and Poor Ventricular Function.** Magdi H. Sami, Vilma A. Derbekyan, and Robert Lisbona

CONGESTIVE HEART FAILURE

512 **Circulatory Autoregulation in Chronic Congestive Heart Failure: Responses to Head-Up Tilt in 41 Patients.** Spencer H. Kubo and Robert J. Cody

VALVULAR HEART DISEASE

519 **Accuracy of Evaluation of the Presence and Severity of Aortic and Mitral Regurgitation by Contrast 2-Dimensional Echocardiography.** Cheryl L. Reid, David T. Kawanishi, Charles R. McKay, Uri Elkayam, Shahbudin H. Rahimtoola, and P. Anthony N. Chandraratna

525 **Two-Dimensional Echocardiographic Determination of Right Atrial Emptying Volume: A Noninvasive Index in Quantifying the Degree of Tricuspid Regurgitation.** Nicholas L. DePace, Jian-Fang Ren, Morris N. Kotler, Gary S. Mintz, Demetrios Kimbiris, and Peter Kalman

530 **Influence of Volume Loading on Intraoperative Hemodynamics and Perioperative Fluid Retention in Patients With Valvular Regurgitation Undergoing Prosthetic Replacement.** J. Gilbert Stone, Paul F. Hoar, and Hoshang J. Khambatta
